A few years ago when labour had to be artificially induced, the membranes were separated—they were punctured—a bougie was inserted, or some other means were used to provoke uterine contraction, and the rest was left to chance. The physician went home till labour had fully set in. This might occur in from twelve hours to a week, there being no certainty about it. The child was often expelled without warning; and any untoward circumstance, such as prolapse of the cord, or a malpresentation, caused its death. Now an induced labour can be so managed as to limit and define the time expended, so that as Dr. Barnes quaintly says—"It is just as feasible to make an appointment at any distance from home to carry out at one sitting the induction of labour as it is to cut for the stone."

The necessity or advisability of this operation can only be judged of, in the case of obstruction, by an examination of the pelvis, or by the history of antecedent labours. In the following case I was amply justified, I apprehend, in having recourse to this particular mode of operative interference.

Mrs._ aged 32 years, has been married eleven years. She had seven previous pregnancies. One, the first, terminated naturally. During her second pregnancy she fell down a flight of stone steps, alighting on the sacrum; was considerably injured, and confined to bed, by the fall. Gestation, however, went on till full term, but labour had to be terminated by craniotomy. Her third and fourth pregnancies ended in abortion at about the end of 3 months. Her fifth went on till full term, when craniotomy was again resorted to. Her sixth was a 7 months' child, labour in this

instance being artificially induced, but the offspring perished in the birth.

At the termination of her seventh pregnancy at full term, she came under my care for the first time; when, after consultation, I performed craniotomy, this being the third time she had been subjected to this operation. During my attendance on her I examined the pelvis to find out the nature of the obstruction, and discovered that the promontory of the sacrum protruded across the brim of the pelvis, reducing the antero-posterior diameter. Whether this was the result of the fall already referred to, or was an ordinary malformation, I cannot say—probably the former, since the first labour terminated naturally.

After her recovery, I advised her, should she have the misfortune to become pregnant, to consult some medical man, giving him the history of her case, 3 months at least prior to full term, so that a living child might possibly be extracted, that her feelings as a mother might not be outraged, and that the doctor might be saved from the performance of a revolting and disagreeable duty.

In a short time she again became pregnant, and at the end of the third month of gestation I was sent for, and found her suffering from uterine pain and hæmorrhage, threatening a miscarriage. I congratulated her on the prospect of getting off so easily this time, but notwithstanding her previous obstetric experience, so intense was her love of maternity, that she begged of me to try and avert the impending calamity. Under the influence of rest and opium the hæmorrhage ceased, the pain subsided, and pregnancy went on as usual. She then engaged me to attend her in her approaching accouchment, giving me *carte blanche* as to what means I should employ.

Dr. Barnes' theory on this subject is so plausible, and the results of his practice so satisfactory, that I determined to put them to the test of experience. I accordingly followed his instructions to the letter, both as to the time and the method of induction.

First, *as to time*. He divides gestation into two parts. "During the first part, terminating at 6½ or 7 months, or at the end of 180 or 200 days, it is scarcely probable that a viable foetus will be expelled. To induce labour within this period is really to bring about abortion. Between 200 and 230 days is a period of very doubtful viability, and the physician should postpone interference until after the latter date, when the operation may be undertaken in the interest of both mother and child." The best time, he says, is "250 days after the termination of the last menstrual period, when the cases are few in which with ordinary care a child may not be delivered alive."

Second, *as to method*. He introduces an elastic bougie into the uterus at night, allowing it to remain till the following day, when uterine action will usually have set in. At an appointed time in the evening he

proceeds to accelerative means, using for this purpose hydrostatic dilators; but as you are all doubtless familiar with his method, I need not further explain it.

Reckoning from the date supplied by my patient, the 250th day occurred on the 31st October last. Accordingly, at 8 p.m., on the evening of the first November, I inserted an elastic bougie between the membranes and the uterine wall, pushing it up for about six inches, coiling up the lower end, and in order the more effectually to keep it in situ I plugged the vagina (this latter was perhaps unnecessary, and is not recommended by Barnes). I then administered an aperient, and told her if the plug or the bougie came away to send for me. Everything remained as I had left it till the next morning. I called at 11 a.m., and found that slight pains occurring at long intervals had set in.

To remain in bed, and send for me when the pains became stronger. Was sent for at 2 o'clock on same day, and found the pains increased in force and frequency and the os slightly dilated. I now proceeded to accelerative means. After some difficulty I succeeded in introducing number 2 dilator, and expanded it with tepid water. The act of introducing I found difficult. The os was so high up that I could barely reach it with the index finger of the left hand, and when I attempted to introduce the dilator into the uterus, on a metallic rod, as directed, the os receded beyond my reach; and it was not until I had introduced the left hand into the vagina, that I effected my object. Once in, however, and distended with water, it did its work admirably.

In an hour the os was dilated to an extent equal to the diameter of the medium bag, and the latter was expelled by uterine action into the vagina. Having now felt that the presentation was natural, I adapted a binder to the abdomen, to keep the head in apposition to the cervix, and prevent the cord from being washed down by the escape of the liquor amnii, ruptured the membranes, and allowed part of the water to escape.

I next introduced the largest bag—this time without difficulty—and sent for Dr. Croker, who had kindly consented to be present at the termination of the labour. On his arrival, the os was fully dilated, and as the pains were now strong, and the head unable to pass the brim unaided, I applied the forceps, and without any trouble delivered the patient of a living child. The placenta gave no trouble; the patient was able to leave her bed in a week; and the child is now strong and healthy.

Dr. John Moore said he looked upon the operation for the induction of premature labour as one of the greatest triumphs of surgical art, an operation that saves lives which must be sacrificed without it. In a patient of his own, whom he had twice delivered by craniotomy, the induction of premature labour saved

her next child, now a strong healthy boy. He had assisted the President in a case where the pelvis was so filled with a tumor that labour was brought on about the sixth month: in this case of course the child was lost.

Mr. Gribbin stated that he had attended a patient, in whose case premature labour had been induced on a previous occasion, but the child died. She passed through a natural labour, and he could not discover any cause for the previous operation.

The President stated that in the case to which Dr. John Moore referred, the tumor, which was the cause of obstruction, afterwards disappeared, and the woman was delivered at the full period of a living child.

The members were unanimous in thanking Mr. McMeekin for his paper, which they considered a most valuable one.

Dr. McMeekin exhibited at the same time Dr. Barnes's dilators which he had employed in accomplishing delivery.

Dr. Spedding read notes of a case of ligature of internal piles the discussion to which was adjourned till next meeting.

The Fourth Meeting of the Session was held in the Library on Saturday 4th January 1873.

The President in the chair. Members present Drs. Stewart, Murney, James Moore, John Moore, H. S. Purdon, McCrea, Charles, McMeekin, Torrens, J. W. Browne, McKeown, Scott, Messrs. Spedding, Ball, Garde, Aickin, Fagan, Bolton and F. Beck.

Mr. Garde was proposed by Dr. McCrea.

Drs. J. Scott and Croker were elected members of the Society.

Dr. H. S. Purdon introduced a patient suffering from favus. 13

W. H. at 12, admitted at the Hospital for Skin Diseases under the care of Dr. H. S. Purdon, for Favus, which had existed for several years. On examination, the scalp was observed covered with the peculiar sulphur-coloured, cup-shaped eruption characteristic of favus. Some of the crust examined manifestly showed the stroma of the fungus, the *achorion*. Alopecia of a permanent nature was observed on vertex of scalp. The boy was strumous, in which people the secretions, and naturally the perspiration, is acid—just the soil, so to speak, upon which a vegetable growth will flourish. The treatment adopted was removal of hair by Bazin's forceps, then a solution of the bichloride of mercury rubbed in, after which sweet oil was applied.

The following paper on Hæmorrhoids, which was read by Mr. Spedding, at the Third Meeting, was now brought up for discussion, as agreed upon:

In June last a gentleman aged 46, who had resided a number of years abroad, consulted me with reference to his general health, but more particularly hop-

ing to be relieved of old-standing internal piles, which had given him much trouble for several years back. He gave the following history.

Had always been strong and healthy, but, while abroad, had been much exposed to vicissitudes of temperature, irregular life, sleeping in the open air in marshy districts, from which he contracted ague. At this time, about 10 years ago, he used occasionally to suffer much from periodical attacks of piles, which bled a good deal, but, being very strong at that time, he did not mind it much.

At the time I saw him he looked sickly, weak, and worn, face and lips pale, general anæmic appearance, appetite bad, action of the heart slow, feeble, but regular. He had been getting much worse within the past 12 months. Whenever he attempted to walk, even a quarter of a mile, the piles came down and gave him great pain in getting them up again. The most troublesome symptoms were constant tenesmus, and frequent micturition the latter disturbing his rest three or four times a night.

On examining after defecation, an oval tumour somewhat larger than a hen's egg was seen encircling the whole of the anus, the long axis being antero-posterior. This was divided by four sulci into four separate pouches which were of a venous blue colour. A little pressure got all up again, and, on introducing the finger, the four parts of this hæmorrhoidal prolapsus could be felt about an inch and a quarter above the verge of the anus.

I considered that ligature would afford the best means for a radical cure; and, in a few days afterwards, I proceeded in the following manner.

Having cleared out the bowels by an enema, the patient pressed down the whole mass; I then introduced my left fore-finger into the rectum, and having felt the upper margin of one of the piles, the left lateral one, I guided a nevus needle, armed with double strong ligature silk, to that point, and pushed it through the base of the pile, bringing it out at the outer margin of the sphincter, a few lines internal to the junction of the skin to the mucous membrane. The threads were then taken out of the eye of the instrument by my assistant, and each half of the pile *tightly* tied, one end of each ligature was cut, the other allowed to remain outside the anus; the anterior pile was treated in the same manner. I did not think it advisable to touch the right lateral or posterior pile at this juncture, fearing subsequent inflammation, and determined to wait until the first half should come away.

I therefore pushed the entire mass, half of which was ligatured, and the remainder, which was not, back into the rectum, put up a morphia suppository, and gave an opium pill. During this operation there was not a teaspoonful of blood lost, no pain was complained of, except when the needle was being shoved

through, and during the act of tightening the ligature. The patient slept well, had no uneasiness until the third day, when he had retention (partial) of urine, and some pain over the bladder. Warm stupes and a couple of large doses of tincture of hyoscyamus and nitric æther relieved this symptom without the use of the catheter. Ordered one grain of opium night and morning.

4th Day—Bowels opened by castor oil, the untied part alone came down.

6th Day, one ligature and half a pile came away.

7th Day, another; and eighth, the remaining two.

In a few days subsequently I sent him to the country; but before the prescribed time was expired he was back again most anxious to get rid of the remainder of his trouble, as he said he felt “half cured.”

I tied the right lateral and posterior piles, the only remaining ones, on the 12th August, in precisely the same manner as I had done in July. He complained of no pain ten minutes after the ligatures were applied, and had not a single untoward symptom. On the eighth day the strangulated part came away en masse, consisting of four ligatures and four half piles. In a couple of weeks all uneasiness disappeared from the rectum, and ocular and digital examination failed to detect any trace of hæmorrhoids. It is now three months since I have seen this patient, but I had this week a most gratifying letter, in which he contrasts his present with his former unhappy condition.

He has, he writes, grown fat; can walk five miles without feeling fatigued; has not the slightest difficulty in micturition or defecation, which annoyed him so much formerly. He also states that a dizziness in his head, which he had before the operation, has almost left him, and that he does not feel any more uneasiness from his old-standing affection.

The President said Mr. Spedding was anxious to obtain from the members an expression of opinion as to the most effectual treatment of internal piles, and how far any of them had used the clamp, or fallen back upon the old plan of ligaturing.

Mr. Spedding said he might mention that the case was a most inveterate one of ten years' standing. The chief inconvenience of the patient was from the incessant diarrhœa produced by internal piles, and the frequent micturitions. He could not walk two or three hundred yards without a whole mass, the size of a turkey egg, passing down. The application of the ligature was altogether free from pain, except momentarily when tightening it. He had got a letter from him a fortnight ago, stating that he has not the slightest inconvenience or uneasiness, and had perfect control over his bowels.

Dr. James Moore said he had a good deal of experience, and never found the ligature fail when judiciously used. He would recommend it strongly; it was not half enough used.

Dr. Charles said the method adopted in Paris was by inserting a gutta percha tube filled with cold water, and thus applying pressure to the piles.

President.—Do you know anything of the result of such treatment?

Dr. Charles.—All I know is that, as a rule, the French have given over ligaturing, thinking this method preferable.

Dr. Murney said he had practised the application of the ligature a good deal, and he believed it was the only operative treatment to adopt for internal piles. He had been present when other members of the profession made use of acid, or the clamp and he did not think them nearly so satisfactory as the ligature. At the period of the application of the ligature, the patient experiences a little pain; but he did not think he would suffer much if the medical man did not include much of the mucous membrane. He had found that sitting upon a pan of hot water was sufficient to relieve the patient from all annoyance for four or five days. He agreed with Dr. James Moore, and considered the ligature the safest, and best, and least painful or annoying to the patient. Hæmorrhage followed more frequently after the clamp than after the ligature.

Dr. M'Creagh said it was a question in many cases whether the operation should be performed at all. He had seen operations performed when he thought it would have been much better to have left the piles with the patient. A gentleman had proved the value of this opinion in his own person. He had been operated on several times. He said to him (Dr. M'Creagh) one day—“I will have a headache to-morrow morning; when I had my piles I would bleed half-a-pint, and then be all right.” His experience was that the piles were a sort of safety-valve for his liver. There might be cases which would necessitate an operation; but it is a local operation for a constitutional disease.

Mr. Spedding exhibited a foetus, which was examined and commented on by the members present.

Dr. Murney then proceeded with his report on the *post mortem* examination of Isabella Kerr and Jane Toner. Before doing so, he said, a report of the examination had appeared in the public papers; but as the evidence had been given before an unprofessional jury, it was not so full and technical as the members of the Society might desire.

1st January, 1873.—The bodies of Isabella Kerr and her servant, Jane Toner, were superficially examined on Monday, the 30th December, at 6 p.m., by Doctor Dunlop and myself, with a view to form some opinion as to when the murders were committed. Jane Toner lay on her back in the hall, her dress and underclothing were disarranged, so that the limbs, so far as the lower parts of the thighs, were exposed; the face was turned slightly to the left side; countenance pale, expression placid, left arm extended, right close by

the side, fingers of both hands tightly clenched. The rigor mortis was extremely well marked in all parts. The body of Isabella Kerr was arranged with more care, and covered with a blanket and counterpane. The rigor mortis was much less marked, and was evidently passing off; from this we inferred that in all probability Toner was dead a shorter period than Kerr. Yesterday it was elicited by evidence in various ways that in all likelihood Toner was killed about 9 p.m., on the 29th, or 21 hours before our examination. I am of opinion that Kerr was murdered before that, perhaps two or three hours. The *post-mortem* was made at 2 p.m. on the 31st; Dr. Dunlop assisted. Dr. Johnston of Holywood kindly took notes. We found:

The body of Toner was that of a woman aged apparently about fifty years, well nourished. There were no marks of injury on the trunk or extremities. On the right side of the neck were two slight scratches, quite superficial, and at least two or three days old. There was one slight wound in the scalp, half-an-inch long, situated at the vertex, a little to the right side. On reflecting the scalp there was a contused spot, the size of a shilling, about an inch posterior to the left parietal protuberance. On removing the skullcap there was an extravasation of blood, about two ounces in quantity, between the dura mater and the bone. The dura mater was then reflected, and the brain removed; every portion of it was perfectly healthy. No fracture could be found in the calvaria or base.

Chest and Abdomen.—The heart was normal in size; the right side was distended with venous blood; the left was empty; the ventricle was very much contracted; the lungs were healthy; there was not a single pleuritic adhesion. The abdominal viscera were healthy. The stomach contained a quantity of partially-digested food; this was carefully examined for the odour of spirits, or wine, but none could be detected. On examining the vagina, the hymen was found unruptured.¹

Examination of Isabella Kerr was commenced at 3 p.m. Her body was also well nourished, in good condition, a very old woman. There were no marks of injury on the trunk or extremities. The face and forehead were fearfully smashed; the nasal bones were not only broken, but the nasal cartilages were completely driven in to the nasal fossæ. The superior maxillæ and malar bones extensively comminuted. The frontal bone was exposed from a little below the frontal eminences, almost to the margins of the orbits, and was extensively smashed. On pressing the hand on face or forehead, there was the feeling of a bag of pebbles. Altogether a more frightful-looking object can

scarcely be imagined. On reflecting the scalp, two contused spots, each about the size of a shilling, were found situated at the back part of the head. On the removal of the calvaria, there was an extensive extravasation of blood on the surface of the dura mater. This membrane was intimately adherent to the bone at some points, so much so that it tore off in some places. There were two spots of extravasated blood, each about the size of a sixpence, one on the anterior, the other on the upper surface of the right hemisphere. The brain substance was healthy. The fracture of the frontal bone was now found to extend through the outer parts of the orbital plates, converging, passed through the lesser wings of the sphenoid, and met in the sella turcica. The anterior surfaces of both hemispheres were torn by the broken edges. These broken portions were quite moveable. There was no injury to the middle or posterior fossæ.

In the Chest.—The heart was of normal size and appearance. Here again the left ventricle was much contracted. The bicuspid valves were healthy; but the aortic semi-lunar valves were much thickened, and of almost bony hardness. The lungs were perfectly healthy, and here we had another example of an individual without a single pleuritic adhesion.

Abdomen.—All the abdominal viscera were healthy. The kidneys were small, but quite normal.

In consequence of a report that fluid which was found beneath the head of Toner, as she lay in the hall, was, according to some, vomited matter, according to others, port wine, I brought my microscope with me, and while the jury were viewing the house and bodies, made examinations—1st, of this fluid, and found it to be unmistakably blood; 2nd, of stains on the surface of the “salamander,” believed to be the weapon with which the fatal blows were struck, and found them to be certainly blood; 3rd, of hairs on the surface of the “salamander,” and found they were brown in colour, and corresponded with the colour of the hair of Toner; one was fully ten inches long, and was, therefore, most probably the hair of a woman. 4th, an examination of several stains on the inside, and also on the outside, of a waterproof cloak in charge of a constable, and alleged to be the property of Mary Raw, now under arrest. In this case, as the spots were dried, I made two demonstrations, one with simple syrup, the other with plain water. I saw clearly by the microscope that it was blood; but the prisoner states that her cloak was soiled by having been placed incautiously in a butcher’s shop below a dead calf.

Dr. Murney continued to say that in the case of Jane Toner there was but one blow struck. In the other case there was a fearful smashing, and at least four or five blows must have been given. The struggle took place evidently close to the door of the water-closet, to which the old lady had probably gone down

¹ It was currently reported that the perpetrator of the murders was a man, who had left the Croft dressed as a female. The coroner suggested that if this were true, rape might have preceded her death; hence the examination.

Ulster Medical Society
Session 1872–1873
President Henry Martyn Johnston

with a candle in her hand. Lying on one side of the hall was a bed-room candlestick, and on the opposite side an extinguisher and a piece of candle. The struggle was apparently continued from that into the kitchen, where the fatal deed must have been perpetrated, for there are several clots of blood there. On three sides of the wall there are stains of blood. The body, he believed, was allowed to remain in the kitchen, until the murderers had a carouse—for from the number of bottles and other appearances in the house, it was evident they had a carouse. The parties had evidently been in search of plunder, for drawers had been burst open, and their contents littered about. That the parties had slept in the room that night was evident from the fact that lights were seen in the room several times during the night. That they had been sick during the night was evident, as there was a quantity of saliva, or some vomited matter, on both sides of the bed. Two persons had apparently been in the room, as they had used a wash-basin for defecating in, and the defecated matter was from two individuals—the one costive, the other as of a person who had taken medicine.

President.—In Toner's case did you find any fracture?

Dr. Murney.—No.

President.—Do you think her death was immediate?

Dr. Murney.—No. I think it possible, from the injuries she sustained, she might have lived for hours.

President.—In the other case, do you think death was instantaneous?

Dr. Murney said he thought so. One branch of the case he had not mentioned. The body of Miss Kerr was not laid in the scullery or pantry in the way murderers red-handed would have arranged it, for the limbs had been decently disposed, and the body placed upon its back, and a blanket, such as would be used in the kitchen for smoothing purposes, placed over the body and head. It looked to him that this disposition had been made in the morning after their night's rest, shortly before their departure. The explanation of that might be that the kitchen window is low and any person walking on the outside could see the interior, and therefore they carried the body to the nearest apartment, where it could not be so plainly seen from the outside.

Dr. James Moore.—Where did Toner bleed from?

Dr. Murney.—From a small wound in the head at the vertex.

President.—Was there any effusion of blood upon the brain matter?

Dr. Murney.—There were two ounces between the dura mater and the bone.

Dr. Stewart.—Was the expression of her countenance placid?

Dr. Murney.—It was.

Dr. John Moore said he had asked Dr. Murney to bring this matter forward, as he thought it would be a matter interesting to the Society, as a professional body.

After some further discussion, the meeting adjourned. Dr. Murney's further notes in this case, read at a future meeting, are given in this connection, as follows:—

6th January, 1873, 4 p.m.—I have just returned from the Police Office, where I examined with the microscope a stain on a piece of calico, called a "garter," in charge of constable Compton, but could not make out blood globules. As one of the witnesses who had seen the Raws between Holywood and Belfast on the 30th ultimo, had stated that one of the women had a piece of cloth tied round one of her fingers, I was asked by Mr. O'Donnell to look at Charlotte Raw's hand for marks of injury. I found two most trivial abrasions on posterior surface of left index finger, and one on posterior surface of right middle finger; they are fully 8 or 10 days old, and are almost healed.

7th January, 1873, 10 a.m.—Examined with the microscope stains on a dress, and also on a piece of linen in charge of head constable Bodley; made two demonstrations of each; used glycerine and water with two, and syrup and water with two—got blood in each.

The globules were shrivelled and contracted; in one demonstration only did the globules expand, and assume a circular outline. Some very pale stains were shown to me on a chemise which may have been blood; I did not examine them microscopically, as if I had found globules it might have been said they were menstrual.

10th January, 1873, 11 a.m.—Examined spots on a smoothing iron, which was found on the lobby, about a foot from Toner's head; it was given into my charge by the coroner on yesterday. I made four microscopic demonstrations—viz., two with glycerine and water, and two with simple syrup and water; in each case I got shrivelled and contracted blood corpuscles, but undoubted blood. I also found a hair with colouring matter; so I assume it was from Jane Toner. The presence of blood and brown hair on the salamander, and also on the smoothing iron, point to both weapons having been used in the murder of Toner. Miss Kerr's hair was very grey, but her injuries were all on the forehead and face, none of them were on the region of the hair, consequently I had nothing but blood stains to indicate the weapons used in causing her death.

Fifth Meeting of the Society was held in its Museum on Saturday 18th January 1873.

Dr. Murney in the chair, members present Drs. James Moore, John Moore, McKeown, Stewart, McCrea, J. W. Browne, D. Johnson, Charles, Scott and Spedding.

Dr. Spedding introduced a patient with tumour in neck which was considered to be glandular enlargement and likely to end in suffocation.

The patient said the tumour was growing on her neck for seven years. She first observed it beginning to form close to the jaw; but it was gradually getting nearer the middle of the neck. When she first observed it, it seemed almost the size of a cherry; and sometimes it was soft, and sometimes hard.

The Chairman said he would be happy to hear any remarks from any of the members on the tumour.

Dr. John Moore.—It is one of those glandular swellings, and I don't think it is full of fluid, at least of that cystic character. I think the termination of it will be suppuration.

Dr. James Moore.—I would think it is enlargement of the glands. I do not say there is no cystic; but I have my doubts about it. My views lean to its being enlarged glands.

The Chairman.—The result of my examination led me precisely to that conclusion. There may be a little fluid deeply seated; but that it is enlarged glands I am satisfied, at least so far satisfied, that I would not perform any operation.

Mr. Spedding.—About three weeks ago, when she came first, it was far softer, and there were fluctuations; but since I commenced to treat her, it has got firmer in the feel. I have no doubt in my mind there was a large quantity of fluid—it appeared fully that there was, when touched.

The Chairman.—Had I such a case in my charge, my treatment would be, to apply a very weak solution of iodine, with some glycerine.

Mr. Spedding.—I added a little glycerine, but it certainly did nothing for its removal.

Dr. McKeown.—For these glands which are in a state of chronic inflammation, some surgeons have advised excision, as being less likely to produce an ugly scar, than allowing them to suppurate. I have seen a great many photographs of patients operated upon by Dr. Pean, of Paris. He states that the results are most satisfactory, both as regards personal appearance, the improvement of the general health, and the prevention of tedious suppuration; and that he has never had a single bad case. I know of one case in which a suppurating gland was removed by him from below the angle of the jaw, and with the best results. Not a bad symptom followed. I look upon a gland enlarged and inflamed almost as a foreign body, and to be treated as such. In operating in dangerous regions,

Dr. Pean uses the knife as little as possible—he rather gouges or tears the gland out. He prefers security to brilliancy, and the results are altogether in his favour.

Mr. Spedding.—It was my own opinion that it should be removed by the knife.

Mr. Garde was elected a member of the Society on the motion of Dr. Mc'Crea.

Dr. McKeown exhibited several cases of disease of the eye, and read the following paper on iridectomy.

Before entering upon a consideration of the various diseases in which the operation of Iridectomy is indicated, I think it well to give a short sketch of the history of the subject.

Iridectomy has been known and practised since the time of Wenzel, who first performed it in 1780. From that date until the time of Von Graefe, its application was mainly limited to those cases in which the object was simply to make a new passage for the rays of light, and hence the operation was termed “the operation for artificial pupil.” By Graefe it was elevated to the rank of a therapeutic agent, and by his writings, teaching, and practice, it has come to take its place as one of the most useful in surgery.

It is interesting to know the chain of reasoning by which a surgeon comes to adopt a particular operative procedure, not theretofore practised. Previous to the adoption of Iridectomy for glaucoma, he had practised it in cases of extensive ulceration of the cornea, rebellious to treatment, and he attributed its beneficial influence to the diminution of tension, thus allowing the weakened tissue to receive a freer supply of nutritive material, and favouring the formation of a firm cicatrix, through the relaxation of the corneal tissue resulting. Observing that one of the main symptoms of glaucoma was an increase of tension, he inferred that if iridectomy exerted its favourable influence in ulceration of the cornea, through diminution of the intra-ocular tension, a similar action might take place in glaucoma. That the relief of tension should be the aim of the surgeon became evident to Graefe.

He clearly established, by the aid of the ophthalmoscope, which had just been discovered by Helmholtz, the presence of changes in the interior of the eye, which could only be accounted for by increased pressure—viz., spontaneous pulsation of the central artery of the retina, and excavation of the optic papilla.

He believed that the internal pressure was the ultimate cause of glaucomatous blindness, and that the permanent relief of tension should be the aim of the surgeon. He found in numerous cases temporary amelioration, by frequent evacuation of the aqueous humour, and finally resolved to try iridectomy, hoping to secure more permanent results. His hopes were realized. His title to the honour of being the first who gave a thorough description of glaucoma in all its varieties, and of being the discoverer of a successful method of treating it is indisputable.

Various explanations have been offered of the *modus operandi* of iridectomy in relieving tension. I will mention some of them.

1st. That iridectomy exerted a curative influence by diminishing the secreting surface for the aqueous. The ciliary body and anterior part of the choroid, and not the iris, are the main secreting organs.

2nd. That the curative effect results from freeing the iris from the pressure of the lens, which is pushed forward by the vitreous. This view is even more untenable than the first, because glaucoma may occur in eyes in which the lens is absent.

3rd. That iridectomy relieves the choroidal circulation, and facilitates the interchange of fluids between the vitreous and aqueous humours through the exposed zonule of Zinn. I really cannot see how the presence or absence of the iris can in any way affect the transit of fluids through this membrane, which is entirely independent of it.

4th. That, regarding glaucoma as a serous choroiditis, excision of the iris quite up to its peripheral attachment opens up lymphatic spaces behind the attachment of the iris to the membrane of Descemet, which lymphatic spaces communicate with a sort of intra-ocular serous membrane between the choroid and sclerotic, and which is, like other lymphatic spaces, lined by an endothelium; thus, by iridectomy, a communication is made between the anterior chamber and these lymphatic spaces, and the serous hypersecretion gets free from the posterior hemisphere of the eye. This opinion is advanced by Sichel, jun., and is based upon microscopic researches by Schwalbe. Sichel compares iridectomy to a thoracentesis for relief of pleuritic effusion.

5th. That iridectomy exerts its influence, not in consequence of the excision of the iris, but because of the sclero-corneal section; and this opinion is based upon clinical results, obtained by Professor Quaglino of Naples. I am not aware that any explanation of this diminution of tension from a simple sclerotomy has been given by the professor; but Wesker attributes it to the formation of a "cicatrix de filtration,"—meaning by this, I suppose, that the contents of the aqueous chamber filtrate through the cicatrix more readily than through the normal structures, causing thus a permanent drain of the fluids of the eye outwards.

It is evident that the question is far from being settled. The fact, however, that the tension is in most cases diminished by the operation, is now admitted by the most eminent oculists, and the practice of iridectomy has been extended over the whole civilized world.

But Graffe's labours and discoveries, in relation to glaucoma, did not rest here. He showed that the disease might be secondary to many other diseases of the eye, and that in many cases the unfortunate termination of ocular affections was owing to the grafting of a glaucoma upon the original malady. There are few diseases of the eye which may not be the starting point of glaucoma. Amongst them maybe mentioned

inflammation of the cornea, of the iris, of the choroid, retinal hæmorrhage, traumatic cataract, prolapse of the iris, staphyloma pannus, and dislocation of the lens. Most of these cases, however, differ from primary glaucoma in this respect—that the cause of the glaucoma can be traced to some source of irritation, and that iridectomy is not applicable in all such cases; but that the treatment should be rather directed to the removal of the ascertained source of irritation.

For so far, in speaking of therapeutic iridectomy, I have only referred to it as an agent to secure diminution of tension, and applicable to glaucomatous diseases, and to cases of ulceration of the cornea, to lessen even normal pressure. The following is a summary of such cases:—

- (a) Simple glaucoma.
- (b) Acute inflammatory glaucoma.
- (c) Chronic inflammatory glaucoma.
- (d) Secondary glaucoma, resulting from weakening of the cornea through previous ulceration.
- (e) Partial staphyloma of the cornea and iris.
- (f) Corneo iritis, and serous iritis, with deep anterior chamber, increased tension, and contraction of visual field.
- (g) Some cases of pannus.
- (h) In cases of extensive ulceration of the cornea. Here the normal intra-ocular pressure, acting upon the weakened part, retards the supply of nutritive material necessary for repair, and causes greater tendency to extensive sloughing. Iridectomy is meant to diminish this normal pressure, to facilitate the regeneration of the tissue, and, besides, to afford an aperture for the entrance of light, in case the ulcerated part should be opposite the pupil.
- (i) In cases of traumatic cataract, where glaucomatous symptoms arise from excessive swelling of the lens, and pressure upon the posterior surface of the iris, and in which the lens is not so completely cataractous as to admit of complete removal, or in which it may not be deemed prudent from the general condition of the eye to perform the more severe operation of linear extraction, iridectomy may be performed.
- (k) In cases of partial dislocation of the lens, with glaucomatous symptoms, in which a portion of the iris is pressed upon, removal of the section of the iris most pressed upon may afford relief.
- (l) In cases of conical cornea, with the double object of relieving tension, and affording entrance of light by a part of of the cornea least changed in curve.

In all these cases, save perhaps in partial dislocation of the lens, the section should be large, and made in the sclerotic, so that the inner margin of the wound should be quite at the periphery of the anterior

chamber; and the whole of the segment of the iris corresponding to the section should be removed. Each case of partial dislocation of the lens should be judged on its own merits, and if iridectomy should be deemed suitable, the portion of the iris pressed upon should be excised. With respect to the treatment of conical cornea by iridectomy, I may remark that I include it here inasmuch as it has been treated by many in this way; but I am disposed to regard the treatment by producing a central ulceration of the cornea and cicatricial contraction, as having most evidence in its favour. I may note a very important point in the manner of performing iridectomy for partial staphyloma of the cornea and iris. I believe that the great cause of the glaucomatous tendency in this disease is the alternate traction and relaxation to which the healthy iris and, indirectly, its ciliary attachment, is subject, through the variations in size of the staphyloma dependent on muscular pressure during use of the eye. A vicious circle is always in operation. The traction on the iris is the link in the chain whereby variations in the bulk of the staphyloma leads to secreting activity. Therefore, in performing iridectomy, the segment of healthy iris attached to the staphyloma on both sides should be excised. The case of Minnie T_ is an example of the success of this plan.

I have now to speak of another class of cases, in which the tendency of the disease is rather to diminution of tension, and atrophy of the organ, and in which iridectomy has an effect directly opposite to that brought about by it in glaucomatous diseases. You have all, no doubt, witnessed the gradual extinction of vision, and shrivelling of eyes under attacks of iritis, irido-choroiditis, and corneo-iritis. The diseases named, when they take this unfortunate course, have this in common—that the iris is very extensively implicated; that it becomes degenerate by long continued inflammatory processes; that it has extensive attachments to the capsule of the lens; and that the communication between the anterior and posterior chambers has become obstructed. How, you will ask, can you expect from iridectomy, in conditions such as those, an effect diametrically opposite to that which you claim for it in glaucomatous diseases? It is necessary to bear in mind that glaucomatous diseases are characterized by hypersecretion of a serous character, whilst the diseases with a tendency to atrophy of the organ are plastic. The two classes are not absolutely separate. We find cases which form a link between them, which are neither truly serous nor plastic, and which exhibit a change of character in different stages. Thus you may find an iritis so far plastic as to form adhesion, and so much serous as to cause considerable increase of tension. Let us take, however, a typical case, and study the causes in operation. The plastic deposit in the tissues ultimately

interferes with the free circulation in the vessels, and in consequence of their constriction, a stasis takes place in the circulation, the iris loses its normal appearance, and changes in physical character, becoming either fibrous, felty, and very resistant, or so rotten as to tear on every touch of the forceps; the secreting power is diminished, the nutrition of all the humours dependent on the vascular supply suffers, and hence the atrophy. An important factor in the result is doubtless the adhesions. The pupil cannot contract and expand, and hence a constant source of irritation of the iris is in operation. There may be frequent recurrences of inflammation on the slightest cause, and with every attack, fresh lymph deposits, so that, finally, the pupillary margin, if not entirely adherent, becomes so, and the iris, not unfrequently, attached by a considerable portion; and in some cases where the plastic character of the inflammation is very marked and extensive, by the whole of its posterior surface to the capsule of the lens. If any retro-iritic space remains, the communication between the anterior and posterior chambers being cut off, the aqueous humour secreted mainly by the ciliary processes is collected behind the iris, bulges that structure forwards, assists in impeding the flow of the circulating fluid, presses upon the iris, lens, and ciliary, tends to produce a stasis in the choroidal circulation, and leads ultimately to deep-seated complications. The lens may become opaque; the inflammation may extend to the ciliary processes and choroid and then truly the disease becomes one of the most formidable to which the eye is subject, and too frequently to irreparable loss of vision. The tendency of an inflammation of this character is generally to atrophy of the organ. You will readily understand, now, how an iridectomy will, in many cases of this kind, when performed in time, lead to an improvement in the nutrition of the organ, and consequently, to an increase of tension. When the retro-iritic span is not entirely obliterated, or when it is distended with aqueous the iridectomy opens up the communication between the two chambers, restores the balance between the different humours of the eye, relieves the iris, lens, and ciliary processes from pressure of accumulated aqueous, and frees the iritic and choroidal circulation. Before resolving upon iridectomy, however, it is necessary to make a very careful examination of the field of vision. Should the patient, with an eye becoming atrophied, not perceive readily the light thrown upon the eye in different directions, then there is reason to believe in the existence of a detachment of the retina, and in such a case any operation is contra-indicated. So, should the whole of the posterior surface of the iris be attached to the lens, and the peripheral portion be retracted, then experience teaches that generally an iridectomy is not beneficial, either in opening a passage for the rays of light, or in

improving the condition of the organ. There are exceptions, however, to the general rule. The case of R_ M_, appended, is a notable example. He had been completely blind for eight months, from an inflammation affecting the cornea and iris; the pupil was entirely closed; pretty extensive opacities of both cornea, leaving, however, the upper part in the right eye, and the inner part in the left eye pretty clear; left eye quite soft to the touch; anterior chamber almost entirely gone; iris of a dirty colour, and soaked as it were with inflammatory deposit, and adherent to lens by most, if not all, its posterior surface; field of vision in both eyes good. In the left eye I performed two iridectomies; the iris was quite rotten. However, I succeeded in tearing away sufficient of the iris and exudations to make a passage for the rays of light. The pupil did not close, and he came to be able to read number 12 of Quillen's types at a few inches. The operation on the right eye restored vision sufficient to enable him to count fingers readily. The tension of the left eye, which had been so notably diminished, soon reached the normal, and now, after a lapse of two years, his vision has remained in the same satisfactory state as after the operation. I note this case particularly, as it is one in which authors would lead you to believe that the operative procedure should have been extraction of the lens with dilaceration of the iris and false membranes; and I cannot avoid thinking that the iridectomy secured for the patient a result which would have hardly been attained by the operation mentioned. As regards the operation of extraction of the lens, combined with iridectomy and dilaceration of the membranes, I may remark, as a strange fact, that I never saw such an operation performed by any oculist in Paris or London, although for a year I diligently watched their practice, and never missed an operation at which I could possibly be present. There must have been cases enough. I can only draw one inference, viz.—that although we have a few brilliant results recorded, yet they are so exceptional, that oculists with an established reputation deem it more prudent not to interfere, the percentage of failures being so great.

Iridectomy is performed for purely optical purposes in the following cases:

1. Opacities of the cornea over the pupil.
2. Closed pupil, the result of inflammation at some considerable I, time previously.
3. Zonular Cataract.
4. Limited central opacities of the lens capsule.
5. Even in hard senile cataract, with cortical substance not affected.

In one case, that of M_ P_ iridectomy succeeded in restoring vision, when any other procedure would have almost certainly failed.

6. In some cases of partially dislocated lens, iridectomy is performed as a preliminary to other oper-

ations, or as a stage of another operation, or as an essential to the accomplishment of a particular object.

(a) As a preliminary measure before operating for cataract by discission, in persons between 20 and 35 years of age. The lens is less likely, in swelling, to irritate the iris, and cause either a traumatic glaucoma, or iritis.

(b) As a stage in Von Graefe's and some other modes of extraction, to facilitate the exit of the lens, and to diminish the chance of an iritis.

(c) Iridectomy is the usual rule in dealing with cysts of the iris, or foreign bodies lodged in it.

An interesting conversation took place on the cases exhibited, after which the meeting adjourned.

The Sixth Meeting of the Society was held on Saturday, 1st February, 1873, in the Society's Room, General Hospital,—the President in the chair.

The Chairman said some members had suggested that they should go back to the original period of meeting, once every week, which would give them more time for the discussion of the various matters that would come before them. He would be glad to hear the opinion of any gentleman who had anything to say on the subject.

Dr. Cuming said if there could be material enough he could see no objection.

Dr. James Moore said he would like to see weekly meetings, but he would also like to see students introduced. They did so many years ago, and it served as a great stimulus, and been of great service to the students.

Dr. John Moore said a notice was up in the College hall that students were welcome to their meetings.

The Chairman said it might be better to defer the consideration of that subject for a week.

This suggestion was agreed to.

Dr. Cuming, in presenting a specimen of Aortic Aneurism, observed that the case presented unusual pathological interest, owing to the fact that it had become practically cured by treatment. It possessed also some clinical interest from the fact that, although of considerable bulk, equal to a small orange, it had never given rise to any symptoms whatever during life.

The history of the case could be supplied in a few words. The man was in the hospital about six months. He came in with an attack of bronchitis. On examining his chest, he came upon an aneurism of the aorta, of which the physical signs were perfectly clear and manifest. The man never complained of any symptom such as are so usually engendered by aneurism, nor at any time during the remainder of his life was there any sign of pressure on any part. Indeed, he was quite unaware of its existence. He told the patient there was something abnormal there, and the man expressed his readiness to do anything that was con-

sidered desirable. He was put under a course or iodide of potassium, without any apparent benefit. He then tried the plan, recommended by Tufnell, of absolute rest, with the use of a very restricted diet. The man submitted to this, and Dr. H. S. Purdon, who succeeded Dr. Cuming, carried on the treatment of the case in the same way for more than two months. The effect was that the physical signs were remarkably improved when Dr. Cuming again took charge of the wards, but the man's health began to sink, so that although the pulsation entirely disappeared, the patient was in such a condition that it was quite impossible to pursue any form of treatment whatever. His lungs became congested; he got cystic inflammation, and began to sleep badly, and his nervous system was in a state of intense irritation. He gradually sank under his misfortune, without having complained in any way of the aneurism, which had now become so solid that no one could possibly have diagnosed its existence. There was simply, as regards physical signs, an area of dullness at the upper part of the sternum, corresponding to the bulk of the tumour. After his death his friends allowed them to make a *post mortem*, and they found this large aneurism occupying the entire space between the innominate and carotid arteries, and about the size of an orange, which is almost completely filled with consolidated fibrin.

Dr. James Moore then exhibited a case of laceration of the elbow, and pointed out the importance in the operation of keeping the nerve from the end of the stump. He also explained how hospital gangrene had interfered with the success of his operation.

The meeting then adjourned.

The Seventh Meeting of the Society was held on Saturday, 15th February, 1873, in the Society's Room, General Hospital, the President in the chair.

Dr. John Moore proposed that the meetings of the Society be held weekly, so long as there was matter to come before them for discussion.

Dr. Fagan seconded the motion, observing that there was abundance of most interesting matter that might be discussed, and if the meetings were held only fortnightly, several important subjects would have to be omitted.

Dr. James Moore supported the resolution, and said that twenty years ago the meetings were weekly, and were well attended by the bulk of the members of the profession, and by thirty, forty, and sometimes fifty students, who were greatly benefited by what they heard.

Mr. Gribbin moved, as an amendment, that the meeting should continue to be held fortnightly.

Mr. Garde seconded the amendment.

The Chairman put the amendment, which was lost, only the mover and seconder voting for it.

The original motion was then carried.

Dr. John Moore introduced a patient suffering from irreducible dislocation of the thumb. He explained that the patient received the injury by a fall. When brought to the Hospital he was put under chloroform, but nothing would reduce it.

The Chairman.—How did it occur?

The Patient.—One Saturday evening, about 4 o'clock, the wind blew off my hat, and as I was running to catch it I tripped, and threw out my hands to save myself.

Dr. John Moore.—I can replace it easy enough, but it will not remain in its place. It immediately springs back.

Dr. Charles.—There is a peculiar instrument used in Paris for reducing the dislocation of the thumb. Two blades are brought together with leather, and I don't know any way in which you could apply such force to the thumb as by it. The instrument, which is a French one, is not by pulleys.¹

The Chairman.—This is a most interesting case in a practical point of view, for we are to take into consideration his trade and business. Now the point is, would you advise Dr. Moore to interfere further, or just leave it alone, allowing the man to suffer whatever inconvenience may result from the injury? We all know that the difficulty of reducing such cases is very great indeed.

Dr. Wales.—There seems to be very little shortening, and he has perfect power of motion. He can apply his thumb fully to the palm. The projection below does not interfere with freedom of motion towards the palm; and, no matter what his business is, I would let it alone.

Mr. Spedding.—I must express my disagreement with Dr. Wales. I really think that although he has a tolerable amount of power of approximating his thumb to his fore finger, operative interference would be beneficial in the case. I think that possibly excision of the tendon, and perhaps the head of the metacarpal bone of the thumb would be attended with great benefit.

Dr. Bolton.—I think the operation Mr. Spedding refers to would be preferable to letting it remain as it is.

Dr. Charles.—I would be inclined to try reduction under chloroform in the first place, and if that failed, to cut through either one or both of the lateral ligaments; and if that also failed, to remove the head of the metacarpal bone. He would then be able to use his thumb almost as well as ever. He will never have a strong thumb as it is.

Dr. John Moore.—That is what I should be inclined to do, viz., to excise the head of the metacarpal bone; but then the question is whether it is not better to let

¹ [See page 1194 for a description.]

Ulster Medical Society
Session 1872–1873
President Henry Martyn Johnston

well enough alone. He was under chloroform, but it always springs back as if there was some elastic tissue between the bones. Some thought the head of the metacarpal bone was broken and tilted round.

Dr. Charles.—Would a splint not have been of some use?

Dr. John Moore.—No; we thought no splint would be of use.

The Chairman.—I am under the impression that in a case of the kind, it is very much a matter for the man himself; because, if he can follow his trade, I would be slow to suggest an operation.

Dr. H. S. Purdon introduced a patient, the subject of Graves' disease. In explaining the symptoms, he said:—

C_ W_, 35, weaver, and unmarried, was admitted into the Belfast General Hospital on January 6th, 1873.

History.—She states that about three months ago she noticed a swelling in her neck, but which caused neither pain nor uneasiness beyond the unsightly appearance it produced. She was in the habit of drinking large quantities of water, which seems, from her description, not to have been hard or calcareous. Her catamenial periods have all along been perfectly regular, and neither in excess nor in diminished amount.

On admission she was placed under the care of Dr. Cuming, who found she was suffering from Exophthalmic Bronchocele or "Graves' Disease." There was hypertrophy of the thyroid body, soft to the feel, and the right lobe slightly more enlarged than the left, a loud systolic bruit heard on auscultation, a pulsatory thrill all over the surface of the enlargement, palpitation of the heart, and slight exophthalmia; at least the eye-balls were not completely covered by the lids during sleep. The pulsation of the deep-seated vessels of the neck were visible, and there was some stomachic derangement, nausea and vomiting but no diarrhoea. As a rule, the patient was sleepless. She was slightly hysterical and anæmic. Her pulse was very high, 135 pulsations per minute. There was not much difficulty in breathing or swallowing, except when very solid food was taken, which had to be well masticated before being swallowed. She complained of pressure of gland on larynx, voice unchanged, eyes brilliant, and strong light "hurts them," temper irritable.

Treatment.—She was ordered by Dr. Cuming, on the 7th January, the following recipe.

℞ Tinct. Aconitii, ℥ xvi.
Syrup, ℥ iii.
Aquæ, ℥ ii.

Half an oz. every third hour. This lowered the pulse. Subsequently she had chloral to procure sleep; and, to prevent constipation, fluid magnesia, followed by iron. The iodide of lead ointment was applied to gland.

On the 1st February Dr. H. S. Purdon came on duty, under whom she was placed. On February 2nd, he ordered the following. Pulse then 130 per minute.

℞ Tinct. Digitalis, ℥ iiss.
Tinct. Ferri Perchlor, ℥ ii.
Aquæ, ℥ vi.

Half an oz. ter in die, ex aquæ.

She continued to take it, and on February 4th the pulse had decreased to 120. On the 5th it was 100, and on the 12th the pulse was down to 86 beats per minute.

All along she complained of intense thirst, and want of sleep at night, for which she was ordered a draught of bromide of potash, to be taken at bed-time. Since she came into Hospital the swelling of the thyroid has greatly subsided, and the nausea and vomiting have entirely disappeared, the eyes are looking better, and, on the whole, she continues to improve. The pulse is falling steadily.

The Chairman.—How long has she been labouring under this?

The Patient.—It is three months since I first observed it.

Dr. Purdon.—Dr. Wales told me he has had a case of the same disease.

Dr. Browne.—Regarding operative interference in this case, I remember where a case of the same kind was brought to the Hospital, and the case was afterwards taken to a certain medical man, and he tapped the cyst. We had great trouble in bringing the patient through.

The Chairman.—I tapped that case, and I remember my own surprise at the time. I looked upon it as a case of hydrocele of the neck. The patient was brought from the country, from the neighbourhood of Castledawson. On tapping it, a quantity of fluid came out. There was a quantity of serous fluid. I thought my diagnosis correct; but, to my disappointment and surprise, the whole thing collapsed, and in two or three minutes blood began to ooze, and the cyst filled up, and was greatly distended. Then my difficulty was to know whether in tapping it I had wounded a small artery, or whether such was the character of the lining membrane of the cyst, that it immediately poured out blood. It swelled up enormously. Of course I did not know what dangerous symptoms might accrue, and hence I brought the patient here.

Dr. Browne.—Dr. MacCormac's opinion was that the surgeon had wounded one of the arteries, and the only thing that would benefit at all was the application of ice. I know we had ice applied for three days. She had all the symptoms of pyæmia but she rallied.

Mr. Gribbin.—In reference to the present case, I believe that if you follow up the patient's history, you will find she has not got sufficient pabulum, which is sufficient to account for all the symptoms. According to my humble judgement it is not a case of Graves'

disease at all. In fact I might condense in a nut-shell the essence of what I wish to convey, by saying that it is a case that has arisen entirely from an insufficiency of food, and if she was supplied with sufficient food for a while, it is very probable the tumour would disappear. What calling does she follow?

Dr. Purdon—She is a weaver. She is getting good diet now.

Dr. Wales.—I have had a case of a similar character. It is very hard to get positive information with regard to these cases.

In this case, if the sequence of the symptoms continue, it would be hard to say whether it is a case of what is called simple goitre, or Addison's disease. I agree very much with Mr. Gribbin.

A Member suggested the use of iodine.

Dr. Purdon said that in ordinary goitre, iodine had a very beneficial action; but if they gave iodine in cases of what was supposed to be Graves' disease, it was very injurious, and weakened the patient still further.

The Chairman said there were on the paper two or three cases of great interest. He hoped that the students would make a point of attending, for the matter discussed at the meetings was of great practical interest.

The meeting then adjourned.

The Eighth Meeting of the Society was held on Saturday evening, 22nd February, 1878, at four o'clock, in the Society's Room, General Hospital,—the President in the chair.

Dr. Core was elected a member of the Society.

Dr. M'Keown gave notice that at next meeting he would propose that the business of the Society should be done in sections, and that one section shall be a sanitary one, and consist of the medical dispensary officers of the town, or as many as choose to take part in it, who will prepare a report monthly, or bi-monthly, to be published in the newspapers.

Dr. M'Crea said that last year the Society and some committees took a great deal of trouble in preparing a scale of fees. He had been asked several times whether copies of it could be easily procured, but had been unable to answer.

The President.—Here they are on the table. We had them here at the last meeting, when they were distributed to the members.

Dr. J. W. Browne read the following notes of cases of Peritonitis, following the introduction of a tangle tent into the uterus. The first case resembled one of strangulated hernia, a tumour existing in the groin, which, on operation, was found to be an obliterated hernial sac.

Case I.—Mrs. W., aged 46 years, was admitted into the Belfast General Hospital on the 18th January, 1878, under the care of Dr. S. Browne.

She states that she was married when 16 years of age, and had two children; the first child was dead born; the second lived to the age of two years. Since the birth of the last child she had menstruated regularly; the last menstrual period being upon the day of her admission to Hospital. She had always been subject to constipation of the bowels, and usually required large doses of purgative medicines.

On admission, she was found to be suffering from a muco-purulent discharge from the vagina, and complained of great pain over the region of the uterus. The discharge had been persistent for the past six months. Ordered an injection of permanganate of potash, to be used twice daily, which was found to have no beneficial effect. Dr. Browne, upon examination by the speculum, found a patulous condition of the os uteri, and a thick muco-purulent discharge coming from the uterus. He diagnosed the case as one of Endometritis, and ordered an injection of sulphate of zinc and tannic acid, to be used thrice daily; also some tonics. This treatment was continued until the 29th January, without any beneficial result, when Dr. Browne resolved to dilate the os uteri by means of a sea-tangle tent, so as to treat the cavity of the uterus by nitrate of silver or nitric acid.

The smallest sea-tangle tent was introduced at 10 a.m. upon the 29th January, and was removed at 4 p.m. She was ordered an aperient draught, to be taken at bed time.

January 30th, 10 a.m.—Bowels freely acted upon. A large sized tent was introduced, which was intended to remain in situ until the following morning; but it had to be withdrawn at 7 p.m., owing to a severe rigor which supervened.

Ordered pulv. doverii, gr.x. h. s.s.

January 31st, 10 a.m.—Pulse 86. Complains of pain upon pressure over the region of the uterus. There is a profuse muco-purulent discharge from the uterus. She has been vomiting since 8 a.m. Ordered an enema of turpentine and castor oil, which brought away a small quantity of fæces; also

R Calomel, gr. i
Pulv. Opii., gr. ¼
Ext. Gent., q. s.
fiat pil.

One every fourth hour.

R Liq. Morphiae
Spt. Amm. Aromat. ana, ʒss.
Aquæ, ad. ʒi
fiat haust. s.s.

4 p.m.—Vomiting has ceased since she took the draught. Pain over the uterus increased. Pulse 120, temperature 104°. Pills were ordered to be taken every second hour; six leeches to be applied a little above Poupart's ligament upon each side, emp, Lyttæ 5 by 3 inches over the region of the uterus, also an enema of castor oil and turpentine in the evening.

February 1st.—Pulse 100, strong; tongue furred; slept some during the night; vomiting commenced again during the morning; pain over the uterus still continues; blistered surface to be dressed with dilute mercurial ointment, and a light linseed meal poultice to be applied over the abdomen. The enema administered yesterday evening brought away no fæces. The morphia draught to be repeated immediately, and the patient to have arrowroot, brandy, and milk during the day.

6 pm.—Pulse 100 and full; vomiting still continues; excessive pain upon pressure over the region of the uterus. This evening a small tumour was detected in the right groin, which the patient states has existed for the past three months, and has increased slightly since the vomiting commenced. This tumour was diagnosed to be a femoral hernia, and believed to be the cause of the vomiting and constipation.

The patient was brought under the influence of chloroform, and the taxis gently used, but this failed in reducing the tumour.

A consultation was called at 10 p.m., Drs. Murney, James Moore, John Moore, and Dr. Browne being present, when it was decided to operate the following morning, should the symptoms denoting a strangulated hernia continue. The pills were ordered to be discontinued, and brandy and arrowroot to be given during the night. A hypodermic injection of morphia was also ordered, should the patient not sleep.

February 2nd, 10 a.m.—Pulse 110; slept a little; vomiting continued during the night; no motion from the bowels has taken place; pain over the region of the uterus not so intense; required to be catheterized during the night.

A consultation was summoned, and it was determined to operate immediately.

Operation.—The usual incisions for the relief of a femoral hernia were made by Dr. Browne, and the various fasciæ divided. Upon opening the sac it was found to be the thickened remains of a hernial sac, containing a small quantity of straw-coloured serum, and no intestine. Dr. Murney passed a director through the femoral ring into the cavity of the abdomen.

The usual sutures were used to close the wound, and a pad of lint and bandage applied.

After the operation she was ordered—

℞ Calomel

Pulv. aromat. ana, gr.ii.

fiat pulv. s.s.

A poultice to be applied over the abdomen.

1 p.m.—Vomiting still continues. A draught of liq. morphia and aromatic spirit of ammonia to be given at once.

6 p.m.—No motion from the bowels; abdomen tympanitic; vomiting continues; ordered an injection of turpentine and castor oil, to be repeated at

11 o'clock, p.m. if bowels have not acted, also a draught containing brandy and hydrocyanic acid every 4th hoar,

11 p.m.—Vomiting still continues; bowels have not yet acted; enema administered with O'Byrne's long tube, which brought away a little flatus, but no fæces.

February 3rd, 7.30 a.m.—Slept none during the night; vomiting still continues; one minim of creosote was now given every fourth hour.

10 a.m.—No vomiting since 8 a.m.; pulse 110, and very weak; brandy to be continued; the discharge from the uterus has ceased to-day.

3 p.m.—Vomited a quantity of stercoraceous matter. The creosote pill was continued, and champagne substituted for the brandy.

6 p.m.—Champagne seems to remain in her stomach longer than any other stimulant; no motion from the bowels; vomiting continuing.

10 p.m.—Patient very weak, and sinking; vomiting a quantity of matter resembling coffee grounds.

February 4th.—Patient died at 4 a.m.

Post mortem examination, performed by Dr. John Moore, sixteen hours after death:—

On opening the abdomen the bowels were found matted together, and the colon in the right iliac region was firmly adherent to the peritoneum, covering the iliacus muscle, evidently the result of recent inflammation.

There was a quantity of fluid in the abdominal cavity resembling feculent matter, but without the odour of fæces. This fluid was tinged with bile, and mixed with flakes of lymph. The bowels were distended with flatus, and some scybala were found in the upper part of the sigmoid flexure.

An obliterated sac was found occupying the femoral ring. The sac was the size of a filbert. There was no cellulitis or inflammatory action of the uterus or its appendages.

Case II.—A similar case occurred when I was house surgeon to the Belfast General Hospital (1868-69),

A female was admitted suffering from a uterine tumour. The os uteri was very small, and a sponge tent was introduced to dilate it. Seven hours after the introduction of the tent a rigor occurred. Fourteen hours afterwards a very abundant muco-purulent discharge flowed from the uterus. The tent was then withdrawn. The patient complained of great pain over the region of the uterus and abdomen.

In 48 hours from introduction of the tent, the usual symptoms of peritonitis set in, and the patient died. In this case no *post mortem* was held.

Remarks.—In the British Medical Journal, for July, 1871, there is the history of a case of acute inflammation of the hip joint, following the introduction of a sea-tangle tent. Pain in the joint came on a short time after the introduction of the tent. The patient died, and, upon a *post mortem* examination, a large abscess

was found in the hip-joint. There was no pelvic cellulitis.

Dr. Cooper Forster considers that several of the rapid deaths which have occurred after the introduction of a sea-tangle tent, have been cases of rapid pyæmia, consequent upon abrasion of the mucous membrane of the uterus.

The President.—In discussing the cases, we may deal with them together in some points, and separately in others. The analogy between my case and that which Dr. Browne has placed before us lies only in one point, that is as regards the hernia. The point in regard to the uterine inflammation, and whether it was from the sponge tent, are separate points for discussion; but so far as the hernia is concerned, the analogy between my case and his lies in that. This preparation was removed from the patient, who was in the Union Infirmary, on the 14th February, 1872, and who I found was labouring under the symptoms of strangulated hernia. I found a small tumour in the left groin. I had her removed into a small ward, and directed that preparations should be made for operating upon her. I had the assistance of Dr. Murney and Dr. John Moore. We cut down in the left groin to what we thought right to be classified with hernia. However, when we had cut down, we were rather puzzled to know what we had come upon, and we could not well make up our minds what it was. Finding we could not, with safety to the patient, return it, we determined to relieve the stricture, and leave the part lying outside. She lived from the 14th to the 20th, and had still symptoms of peritonitis and strangulation, except that a day or two before her death, copious evacuation took place from her bowels. I made a *post mortem* examination, and found there were symptoms of peritonitis, and a mixture of lymph, which might be taken at first sight for thin fæces. Upon examining the seat of hernia, we found an obliterated hernial sac. Looking upon it as a hernia, and not being able to return it, what we did was to relieve the stricture, and leave it as it was. She died from peritonitis; and I may mention that at one point there was a perforating ulcer, surrounded by a gangrenous state of the intestine. There was another point struck me as a matter of interest, that is, how the old lady lived so long after perforation, Nature was making a bold attempt at effusing lymph in the neighbourhood; but how she lived for six days, after perforation of the bowels, was extraordinary. It is possible there might have been some bowel affection, and that that gave rise to the symptoms, and that the perforation took place during the time she was under treatment in the Infirmary.

Dr. John Moore.—It was not an inflamed tumour. There was that peculiarity which was seen in Dr. Browne's case, that there was a measure of obscurity from the absence of the tenderness you would have expected.

The President.—I think this case resolves itself into two points, so far as our discussion is concerned. It would be a pity we should lose sight of the hernia, which can come up again, and that we should not thoroughly discuss the advisability of introducing these tents into the uterus. I think we should ask the members present what is their experience in dealing with such cases.

Dr. M'Keown.—Though unfortunate cases may occur, in regard to the introduction of the tent, still I do not see that there is any great reason for condemning the practice utterly. With respect to the sponge tent, I think it should be altogether discarded, and I think a clean smooth piece of laminaria digitaria would be preferable. I remember reading some time ago a paper, by Dr. Kidd, on the use of laminaria digitaria, cut into small pieces, and introduced side by side.

Dr. John Moore.—I think, Mr. President, there are a number of cases that have been already recorded of the irritation, and constitutional disturbance, and fatal results following from the introduction of the tangle tent. I think the history of this case is so clear, that I do not know how we can arrive at any other conclusion than that it was the exciting cause. There was a rigor following within a few hours of its introduction. I saw the patient during life, and was present at the *post mortem*. The occurrence of hernial tumour is one of these incidental things that come to be of when we meet them. It is only a warning to us to look out and be more careful in the employment of a mode of treatment that has not unfrequently terminated fatally.

The President.—Some member of the Society stated a case where peritonitis set in from the use of Simpson's sound.

Dr. M'Crea.—That has happened several times.

Dr. Murney, J.P.—I saw both these cases—that operated on by the President, and the one that has been the subject of Dr. Browne's paper. They are the only cases in which I have seen the old hernial sac without contents the subject of an operation. You have arranged that, for the present at least, the discussion should be confined to the uterine branch of the topic. I had under my charge some time ago, a patient in whose case I was desirous of dilating the os, and introducing one of the tangle tents, which was followed with most unsatisfactory results. She had a most severe attack of inflammation. A somewhat allied case is pretty well known to most of us, viz.—where the menstrual secretion is retained. I have operated upon some cases, without any fatal result; but several such are on record, and I fancy it would be a somewhat allied case to that of an operation on the cervix with a tangle tent. I would be much more cautious in the use of either sponge tent or tangle tent now, than a few years ago.

Dr. Brice Smyth.—I have never seen any bad effects.

Mr. Spedding.—Although I have no experience of the tangle tent, I cannot quite understand how we interfere with the uterus so much latterly. I think the recent system is to use intra-uterine injections, and, in fact, to manipulate more freely with the uterus than they were accustomed formerly to do. I think myself, and Dr. Walton Browne will agree with me, that we both very freely use carbolic acid in the dispensary for ulcerations, pass it freely up the cervix, and that has never been followed by any unpleasant result. I have done it frequently, and within the last few weeks I saw Dr. Playfair's suggestion of swabbing the whole of the uterus out with an instrument with a long handle, and inserted as far as possible, with cotton wadding, saturated with carbolic acid. I cannot see why any evil effects should follow the use of the tangle tent, when one can use such a powerful caustic to the uterus.

The President.—Have you found it successful?

Mr. Spedding.—Well I have not found it as successful as one would believe from reading Dr. Playfair's lecture, in point of causing a cessation of the discharge; but I have found it productive of no unpleasant symptoms, such as rigor, &c.

Mr. Gribbin.—What strength do you mix the solution of carbolic acid? Do you form it from the crystal?

Mr. Spedding.—Yes. It is simply dissolved by heat, and kept fluid by a few drops of water, a little glycerine, say a drachm or half a drachm.

Dr. M'Keown.—I think, as a rule, the more powerful, the less dangerous.

Dr. M'Crea.—I think there is, perhaps, a reaction setting in against what Mr. Spedding speaks of. I think the tendency at present is not to interfere with the uterus so much as Sir James Simpson and his pupils did. There is some little risk in using these tangle tents, which is owing to not attending to the size of the tent. If a tangle tent be put in through the canal of the cervix, and be allowed to swell in the cavity of the uterus, the end becomes bulbous, and there is some little difficulty in extracting it. You should select a small tent, as small as can be used, and afterwards come up if necessary. I think the danger is not sufficiently attended to of putting in a larger one,—that forms this bulbous extremity, which causes great difficulty in extraction.

Dr. Murney.—We have to thank Dr. Browne for bringing these cases before us. I do not believe there could be two more valuable cases placed on record than those brought before us to day. They are most valuable in regard to our knowledge of the treatment of uterine affections. I think the fashion of the day, as led by Sir James Simpson, has been rather in favour of too much manipulation, and interfering with the uterus too freely. It is, therefore, much to the advancement of obstetrical surgery that cases of this

description should be placed on record. If every case was recorded, physicians would be more careful than many of them are at present. The other cases of hernia are interesting too, and it might be well to have a further discussion in regard to them at a subsequent meeting. There are so many points in connection with these two cases of hernia, that I would suggest we should take up the matter at the next meeting.

The meeting then adjourned.

The Ninth Meeting of the Society was held on Saturday, March 1st, in the Society's Room, General Hospital—The President in the chair.

Members present Drs. H. S. Purdon, Whitaker, Fagan, J. W. Browne, M'Crea, Torrens, Brice Smyth, D. Johnson, Charles, Scott, John Moore, Messrs. Garde and Spedding and Dr. McKeown.

Dr. M'Keown gave notice that, at next meeting, he would move the following:—"That a Committee, to be called a Sanitary Committee, be appointed to report quarterly to this Society upon the sanitary condition of Belfast; that such reports and the discussions thereon be published in the daily papers, for the information of the public, and of our local boards, and for that purpose that the representatives of the press be admitted. That such of the local officers of dispensaries and charitable institutions of this town as are members of this Society shall be ex-officio members of the Sanitary Committee."

Dr. Henry Samuel Purdon introduced a patient suffering from progressive muscular atrophy, and read notes of the case:—

The President.—What age is the patient?

Dr. Purdon.—About fifty.

The President.—He does not look that. We will be glad to hear any remarks on the case.

Dr. Fagan—I think the subject has been well nigh exhausted by Dr. Purdon; but it seems to me that, in such cases, we are frequently disposed to look to the nervous centres rather than to the peripheral extremities. Where the thing is local, very often the origin of the disease is in the extremities, and not in the nervous centres; and, if treatment were more specially directed to them, we would, I feel sure, have frequently better results than at present. This condition frequently occurs from too much heat or too much cold interfering with the intimate processes that go on in the tissues, the nerve supply being somewhat interfered with, wasting going on, and a corresponding repair not carried on in it. That is indicative of the disease being in the peripheral extremities; and if physicians directed their attention to them rather than to the nervous centres, their treatment would be often attended with better results.

Mr. Spedding.—I think this a typical case of the disease, and I am afraid that the prognosis is very serious for the patient, inasmuch as he is getting

gradually worse, and it has lasted above the ordinary mean duration of fatal cases. I think the mean duration of fatal cases is under $5\frac{1}{4}$ years from the commencement of the disease. Roberts has analysed 106 cases, in the course of which he ascertained the mean duration to be five years and two months. Duchesne has advocated the galvanization of the inferior vital ganglion of the sympathetic, and he has stated he has seen good results from the vital ganglion being stimulated.

Dr. McCrea.—I think we could hardly expect much from that. There have been few post mortems in connection with this disease—only 12 or 14, I believe. In two of these cases the cord was examined by Dr. Lockhart Clarke. To examine the cord properly is a difficult pathological work. In these cases, there has been found disease of the anterior roots, and in some of the cases degeneration of the spinal cord. I think we may infer from the few cases in which post mortems have been held, that if they were more general in cases of this kind, disease of the spinal cord would be found in most cases. There is hardly evidence that the disease was a peripheral one. In those cases where something was observed in the spinal cord, it was observed without any minute examination. I would be slow to agree with the statement of Dr. Fagan that this is a peripheral failure. As to treatment, if anything is to be gained, it will be by stimulation of the muscles.

Dr. Browne—From my reading, I believe the disease to be central instead of peripheral.

The President.—I have had an opportunity of observing three cases—one of them lay for a long time in the lunatic department of the workhouse. The appearance of the upper extremities was a fac-simile of the case that has been shown to the Society. The muscles of the lower extremities became atrophied by degrees, and the patient sank by gradual exhaustion. There were no symptoms that developed themselves of any disease of the nervous centres.

In another case the patient came to me from Portadown; and the third case is at present in the Union. In the last case the disease is now rather in the incipient stage. The patient did not come in to be treated, but finding I was likely to discharge him, he drew my attention to the drooped condition of his hands. My experience in the other cases led me to look at the ball of the thumb; for from my experience the atrophy commenced in the muscles of the ball of the thumb. The disease has not progressed further up than the elbow. If I can keep hold of him, I will be glad to bring him down, and to show him to the Society. I must say there certainly seems to be a complete freedom of any disease of the nervous centres. One is led, in looking at the cases, first to enquire as to whether they had been in the painting trade. We have not much to boast of in the way of treatment. Unless we

had a very good patient, we would scarcely persevere so constantly with electrifying as to lead to any practical result. I am afraid we could not take the credit to ourselves of pursuing that treatment to a satisfactory issue in the hospital. I would be inclined to think that the disease is paralysis of the muscles, from lead. Some of the patients complain of neuralgic pains.

Dr. Purdon.—The patient complained of something like an electric shock passing from the middle-finger up.

The President.—Have you tried electricity?

Dr. Purdon.—Yes; for three months, but with no beneficial result. I think cod liver oil is a good thing.

Dr. McCrea read notes of several cases of idiopathic neuritis:—

The recorded cases in which distinct evidence of Idiopathic Neuritis of spinal nerves has been obtained are not numerous. Among them are three or four cases of Herpes described by Barenprung, and others, in which, death having occurred from other causes, post mortem examination revealed serious lesions of the nerves supplying the herpetic parts. Barenprung's theory is that the herpes depends on irritation of trophic fibres, which start from the ganglia on the posterior roots. He does not, however, consider that grave disorganisation of the nerves is necessary to explain all his cases, for he cites some as examples of the results of peripheral irritation. Similarly, Dr. Lockhart Clarke (see his article on Diseases and Injuries of Nerves in Holmes's System of Surgery) does not look on Neuritis as the only nerve disorder which causes herpetic eruptions, for he speaks of these as resulting from neuritis and neuralgia. And, indeed, the general retention of the terms Herpes Zoster and Unilateral Herpes, shows that no very settled opinion is held as to the nature of the change in the nerve.

I have endeavoured to gain some information on this point by examining carefully some cases of the disease in a more advanced stage than that in which they ordinarily come under notice: that is, after the healing of the skin. I need hardly say that many observers have remarked the occasional occurrence of annoying sequelæ, such as numbness, tingling, pain, hyperæsthesia, and anæsthesia. But I think a mistake has been committed in considering these as occasional, passing and non-essential. In *all* advanced cases that I have seen, local nervous derangement, more especially anæsthesia, has supervened at some period, and has persisted.

I have seen, during the last two years, twenty cases of Herpes following the course of nerves. Of these, one is still recent; one is in a child, from whom I have not been able to obtain satisfactory information; and seven others I have lost sight of and been unable to trace. The eleven remaining I have examined in their advanced stage. In none has the cuta-

neous affection appeared be either the beginning, the end, or the principal part of the process. Herpes Zoster and Unilateral Herpes are quite inadequate expressions, not to speak of the special inaccuracy conveyed in the terms "Zoster" and "Unilateral." The necessity for a new name for the disease becomes more evident from the consideration that herpes is not the only cutaneous phenomenon known to be associated with local nerve affections; for lichen, acne, pemphigus, urticaria, and erysipelas, as I have myself seen, have, at times, a similar association.

After the healing of the skin, the general condition of the part may be described as presenting hyperæmia, pigmentation, and hyperæsthesia. Then the vascularity diminishes, there are depigmentation, and anæsthesia. These two sets of conditions may be found mixed in different proportions, according to the stage which the disease has reached.

Case 1. A woman, aged 30, was first seen on December 18, 1872. A zone of skin, 3 inches broad, entirely destitute of pigment, extends around the body above the umbilicus. It completely surrounds the body, except a handbreadth at the spine. The upper and lower edges of the zone, which are almost straight lines, are not darker than the neighbouring healthy skin, as sometimes occurs in leucoderma. Every part of the zone is completely insensible to pricking and pinching. She says that seven years ago she was seized with an acute pain in this region, that a "red flash" appeared on the site of the present whiteness, that then an eruption "like pox" came out all over it, that this eruption never extended, and that it faded away slowly, and was followed by anæsthesia and blanching. She gave this history without any leading questions from me, and the inverted commas mark expressions of her own.

Case 2. A girl, aged 17, was seen on December 14, 1872 for amenorrhœa. I noticed on the right side of the chest and below the level of the axilla, a characteristic series of herpetic marks extending from the spine to the middle line in front. Some of them are pits, but most of them are merely blanched spots. The point of a pin when pressed with considerable force excites almost no sensation in some of these, and in all the sensibility is far below that of the surrounding skin. The disease commenced six years ago, when she was told by her medical attendant that she had shingles. She has quite recently complained of numbness of the right leg. A year before the appearance of the eruption, I treated her for chorea of the right side. Mr. Hutchinson, in the second series of cases of Shingles, attributed by him to Arsenic (*Med. Times and Gazette*, 1869, Vol. I., Case 14) mentions, without, however, tracing any connection between the two diseases, a case in which chorea and shingles occurred in the same person. Dr. Borelli, of Turin (quoted in Dr. Brown-Séquard's article in Holmes's System of

Surgery) records a case in which neuroma and chorea were intimately associated. I saw lately a case of neuralgia, in the site of an extracted tooth, in which each recurrence of the neuralgic fit (it came on once in the twenty-four hours) was associated with violent, involuntary rhythmical movements of the arm and leg of one side. So that the connection hinted at above between the shingles and the chorea is not so fanciful as at first sight it looks.

Case 3. A boy, aged 8, was brought to the Dispensary on April 22, 1872. The right side of his neck was covered with an eruption of Herpes. The cutaneous branches of the upper cervical nerves were all represented by the ramifications of the herpes. The courses of the superficialis colli, the auricularis magnus, the occipitalis minor, and of the acromial and cervical branches of the cervical plexus, were sketched by vesicles on the skin. On December 23, I examined him. A multitude of white marks were seen in the site of the herpes. Portions of the original eruption have left no vestiges, and no nervous grouping can now be traced. Some of the spots are quite insensitive; all are much more so than the surrounding skin. This is a comparatively recent case; in which it would be rash to infer that the changes are complete.

Case 4. A girl, aged 9, came to the Dispensary with a zonular herpes on May 30, 1872. The eruption, preceded by a few hours of severe pain, had appeared the day before. It surrounded the body, except a handbreadth at the middle line in front. The lower edge of the zone was two fingers' breadth above the level of the umbilicus. In the handbreadth above this, on the right side, was a half zone of white spots, evidently representing an old herpes. I again examined this child on January 2, 1873. In the white spots of the old herpes, sensation was very much deadened. The new one was red and very sensitive, except a few spots here and there over it, which were less sensitive than natural.

Case 5. A man, aged 60, was first seen on June 7, 1872. A severe pain in the right side ushered in a dorso-intercostal herpes of the same side. On December 26, the only traces left of the original eruption were a few white spots, much more insensible than the surrounding skin. He had considerable pain in a zone above the herpes.¹

Case 6. A girl, aged 4, was seen on January 7, 1873. Her mother stated that eight months ago she had had shingles. She had, when I saw her, a dark coloured

¹ Since I wrote the above I saw two recent cases in which an allied phenomenon occurred. In one, a case of inferior intercostal herpes, deep pressure with my finger in the spinal groove caused a pain in the epigastrium on a higher level than the eruption; movements of the patient's body produced the same effect. In the other case, one of superior cervical herpes, when the finger was, with firm pressure, run down alongside of the superior cervical spines, a pain was felt in the occipital region, at a spot where there was no eruption.

half zone, with irregular edges, passing around the body and slightly downwards from the spine to the sternum, crossing the inferior angle of the scapula and passing below the nipple. The dark zone was thickly mottled with white spots. Some of them were pits, but the majority appeared only as patches of whitened skin. Although a pin was firmly pressed against the white spots, the child never winced. When the pin was pressed with much less force on the healthy skin the child instantly cried out. The brown skin was, in several places, unduly sensitive.

Case 7. A woman, aged 45, was seen on May 5, 1872. She had a right herpes, commencing at the spine, passing around the body slightly downwards, below the mamma, and on to the middle line. She has had uneasy sensations in the side ever since. She was again seen on December 24. The half-zone shewed extensive white spotting on the dark ground of her natural complexion. The insensibility of the spots is great everywhere, but more so in front. In this case, as in others, on applying the point of a pin alternately to the healthy and diseased parts it was necessary to accompany each touch by a word. I said "That," and "That." Otherwise, at those times when no sensation was excited, the patient would be confused. The value of this simple expedient will be fully appreciated on trial.

Case 8. A woman, aged 40, was first seen on October 7, 1872. After a night of severe pain there appeared a half zone of herpes, reaching from the lower dorsal vertebræ, around the left side, downward and forward toward the umbilicus. There was sharp fever.

On December 24, the eruption had faded, leaving a half zone of marks—those in front white, those behind red. The white ones had lost sensation; the red ones were little different from the surrounding skin. Marked tenderness, on deep pressure at the spinal end of the herpes, persisted.

Case 9. A woman, aged 40, had been treated by me in the beginning of 1872, for syphilis. I again saw her in September. She then had a series of herpetic crusts, commencing on the right side near the lower lumbar spine, passing across the right iliac crest in a slightly curved direction to the trochanter, and throwing out a few crusts even below the trochanter. There were also a few crusts above and in front of the anterior superior spine of the ilium, and a few nearer the middle line, and on a lower level than the last. It was undoubtedly unilateral herpes. At the same time there was commencing paralysis of the right limb and numbness of the left. There was acute pain referred to the right external iliac region; this I considered the herpetic pain. Iodide of Potassium was prescribed for her. I then lost sight of her for a considerable time. I afterwards found that she had become unable to come to the Dispensary. After a difficult search for

her, she came to me on January 16. I found that after leaving me she had completely lost the powers of sensation and motion in the lower extremities; she had then improved under the use of Iodide of Potassium. On the above date there was no general anæsthesia or paralysis of the limbs. The herpes had left much fewer traces than usual. These were whitish spots that could barely be distinguished from the surrounding skin. In a few of them sensibility was dull, but in the majority I could detect no difference from the sensibility of the region. Points of interest in this case are that the herpes was associated with a grave neurosis; that it appeared not on the side of dulled sensation, but on that of acute pain; and that it underwent a much more favourable course than usual, this result happening under the use of Iodide of Potassium.

Case 10. A boy, aged 13, was seen on January 16, 1873. Two years ago he had a unilateral lumbar herpes preceded by severe pain. The affected skin remained red for a long time. At the date of examination the white marks were large and numerous beyond the common. The insensibility was greatest in the anterior spots, and existed in many places between the spots. There was no spinal tenderness.

Case 11. A man of sixty was first seen for Hepatic Abscess in November last. He had been jaundiced for a year. He called my attention to a loss of power in the upper arm. He could flex the elbow and carry the arm across the chest. He could not raise the arm from the side, draw it backwards, or extend the elbow. The muscles of the shoulder and arm were much wasted, especially the deltoid. There was a severe pain, referred to the point of the shoulder. An almost linear herpes reached from the interpinos space below the vertebra prominens, across the spine of the left scapula. It continued in the same linear form down the back of the arm, and the outer side of the forearm to the wrist. There was tenderness on deep pressure at the spinal end of the herpes. On January 18, the eruption had almost disappeared. The wasting of the arm had progressed. There was hardly a vestige of the deltoid left. The general mal-nutrition of the arm made it difficult to obtain evidence as to whether the anæsthesia in the track of the herpes was greater than in the surrounding skin. At no period in the case did the patient's keeping his eyes fixed on the arm facilitate movement. Nor did faradisation appear to have the least effect on either the deltoid or triceps. This case runs counter to Barensprung's statement that herpes is not associated with paralysis.

The preceding cases present the following noteworthy features—

1. In all, there was evidence of disorganisation of the nerves of the affected part.

2. In one, the disease could not be considered as confined to the posterior root of the nerve, for the efferent fibres had also ceased their function.

3. In two cases there was association with a general neurosis.¹

My cases also illustrate several other interesting points in connection with herpes, on which, however, I need not dwell, as they have been noticed by previous observers. Those who wish to obtain further information will find full summaries and copious references up to a recent date, in Dr. Lockhart Clarke's article on Diseases and injuries of Nerves, in Holmes's System of Surgery, and in the last edition of Dr. Tilbury Fox's Skin Diseases. The *London Medical Record* also has given an account of some still more recent foreign papers on ophthalmic herpes.

After observations from several of the members on Dr. M'Crea's paper, the proceedings terminated.

The Tenth Meeting of the Society, for the present Session, was held on Saturday evening, March 8th, in the Society's Room, Belfast General Hospital. Dr. H. M. Johnston, President, in the chair.

Dr. MacCormac, Ann Street, was elected a Member of the Society.

Dr. M'Keown, in pursuance of notice given at a previous meeting, moved:—

1. "That a Committee to be called a Sanitary Committee be appointed to report quarterly to this Society upon the Sanitary condition of Belfast; that such reports, and the discussions thereon, be published in the daily papers for the information of the public and of our local boards, and that for that purpose the representatives of the press be admitted."

2. "That such of the local officers of dispensaries and charitable institutions of this town, as are members of this Society, shall be ex-officio members of the Sanitary Committee."

Dr. M'Keown went on to say,—For some time before the beginning of the Session he had intended to bring forward a motion with a view to having some radical changes made in the constitution of the Society, as it was well known it did not work so satisfactorily as could be desired; but as the President was appointed to the position he held, so as to endeavour to put new life into the Society, he deferred taking any action in the matter.

Besides, he thought it better that changes should be introduced gradually, and not hurriedly. It struck him, however, that there was one change or improvement which might now be introduced with advantage. He thought it would be desirable to graft on the Society a Sanitary Committee for Belfast, and the more so, as sanitary matters were at the present time receiving special attention from Government and Societies in large towns, as in Dublin. Well, if attention to such matters were necessary anywhere, it was in Belfast;

for he thought few towns in Ireland were in a worse sanitary condition, as the medical officers of the dispensaries could testify. He often felt, when administering medicine to dispensary patients, that it was useless to give them medicine so long as they lived in the places they did, where the light of the sun was excluded, and where they were constantly surrounded with filth and dirt, and pollution of every kind, and where the atmosphere was reeking with dreadful odours, and filled with smoke—where everything was calculated to generate and propagate disease. These poor people could not help themselves. The medical officer might give them whatever directions he pleased; but in many cases without the least benefit, owing to the dreadful surroundings of the patients.

Any of them who had read with care the reports of the sanitary officers of the Town Council, would feel it was the merest sham. They would see in the reports that in a particular district so many houses had been whitewashed, so many pigs killed, and information of that description, whereas they all knew that one could not turn into any quarter of the town without having all the senses offended. He believed that the neglect of sanitary matters was the principal cause of disease in the town; the other great causes being intemperance and immorality. If the sanitary condition of the town were improved, and the two other matters he had referred to attended to, there would be very little disease, and affairs would look very gloomy for the doctors. He suggested therefore that the dispensary medical officers, who know most about the condition of the poor and the causes of disease in operation, should be appointed members of this Committee, whose reports should be drawn up quarterly and submitted to the general public, and not merely to the members of the Society. If this proposal were adopted, the Town Council would have very little excuse for not having the town put in proper condition, and the sanitary officers would be stimulated, and owners of property would be coerced into keeping their houses in good repair, first through fear of exposure, and then through fear of loss. Dr. M'Crea made an admirable suggestion with respect to the way in which such a report should be made out. It was that a list of the poor streets of the town should be printed, and that each medical officer should note opposite the streets the nature of the disease there prevalent, even specifying the numbers of the houses. The constitution of the Sanitary Committee should, he thought, be pretty much as he had indicated. At first he thought the medical dispensary officers should be the only members of it, but afterwards it occurred to him that the medical officers of public boards in town could render valuable aid. He also thought it would be well to add one or two other members of the profession in town. He did not feel it

¹ A curious remark is made by Schwartz (*Diss. de Zonâ Serpiginosâ Halæ*, 1745, p. 17) who says that he saw three instances, which followed violent fits of passion.

necessary to say anything more on the subject, but was sure the matter would commend itself to their judgment, as calculated to render good service to the town.

The President had no doubt that in a short time a good deal of attention would be directed by Parliament to sanitary legislation, and he thought it would be for the benefit of the Society if it did something to show its position, and the services it was calculated to render to the sanitary condition of the town.

Dr. John Moore had much pleasure in seconding the resolution. He had taken some interest in this question, and had for a number of years been trying to bring it before the Society. About six years ago, it would be observed by reference to the reports, that he brought forward a motion, which was seconded by Dr. Hill to the effect that application be made to the Registrar General for a fuller account of the causes of mortality in Belfast than that published. He believed that the movement then made resulted in their getting a tolerably satisfactory weekly report of the causes of death.

Dublin had been for some years previously in possession of a tolerable statistical account of the causes of death within its bounds. The movement then made by the Society resulted in getting weekly returns, and they now got returns of the number of deaths from small pox, measles, fever, &c., which were accessible to all. They could take a still further step in advance, and get a registration, not only of deaths but of diseases, for slight epidemics passed over the town frequently, inflicting a great deal of disaster. The registration not only of deaths but of sickness would be a desirable thing. In seconding the motion, he merely endorsed the general principle, without binding himself to all the details. As to what had been said about the publication of the reports, that might be settled at a future stage; the details could be arranged afterwards.

Dr. M'Crea.—I think the carrying out of the suggestion contained in the resolution would be most useful to the community. There will perhaps be a little trouble in starting the matter, but I think it is worth all the trouble. The registration of diseases I consider more important than of deaths. At the dispensaries we have warnings of rushes of disease, before the ordinary practitioners of the town generally are made aware of them, and we have warnings of the decline of certain diseases before others—indeed we are in possession of a large amount of information, which, for want of being tabulated, is allowed to go to loss. If the Society adopts any means of making that information available, it will be conferring a great boon on the community. I would hardly be disposed to agree with the proposition to admit the press, as it would give an opening to a number of movements I would have an objection to. We could achieve all the objects that are

to be gained, by furnishing our own reports to the papers, if necessary.

Dr. M'Keown.—That is not necessarily an essential part of the resolution.

Dr. M'Crea.—Otherwise I join heartily in the movement; indeed I have spoken about it several times, and consider it calculated to effect much good. It will no doubt be a little troublesome, but it may be put into such a shape as to give little trouble to the dispensary men.

The President.—I have no doubt that if once started, and in action, it would be both appreciated by, and bear weight with, the authorities of the town.

Mr. Spedding.—Is it the wish of the Society that the Committee should be formed?

The President.—I have heard no objection offered yet.

Mr. Spedding.—We have already a great deal of gratuitous labour—indeed, we have plenty to do; but if this would be the first step in leading to the appointment of a medical officer of health for the town of Belfast, I would support it.

Dr. M'Keown.—Lord Hartington will bring in a bill in reference to it this Session, and it is likely the dispensary officers will be the officers for the district. So, the sooner they get into harness the better.

The President suggested that Dr. M'Keown and Dr. M'Crea be requested to act as secretaries to the Committee, and that they also be requested to draw up a scheme for the working of the movement, and obtaining the required information. Both gentlemen intimated their willingness to accede to the President's suggestion.

Mr. Spedding asked what duties would be expected of the Dispensary officers.

Dr. M'Crea said they would be on the Committee, and would consequently have a part in fixing those duties.

Dr. M'Keown.—The duties will resolve themselves to this; viz, to putting down the names of the places in your district you consider defective in sanitary arrangements, and the diseases you attribute to those defects; and, with a view to fixing a mark on the right quarter, in some cases the numbers of the houses that are nests of disease will require to be specified. All the medical officer will have to do, will be to black-ball the bad ones, for the list of the streets will be made out, and furnished to him. The resolution was then passed in the following form:—"That a Committee, to be called a Sanitary Committee, be appointed to report quarterly to this Society upon the sanitary condition of Belfast; that such reports be published in the daily papers, for the information of the public, and of our local boards; (2) that such of the medical officers of dispensaries and charitable institutions of this town as are members of this Society shall be ex-officio members of the Sanitary Committee."

On the motion of Dr. J. W. Browne, seconded by Dr. Brice Smyth, the names of Dr. Wales and Dr. David Johnston were placed on the list of the Committee.

Dr. Brice Smyth then read the following notes of a case of puerperal convulsions:—

As puerperal convulsions is one of the most frightful and dangerous complications of parturition (though fortunately not a very common one) I thought that a few notes of a case that occurred under my care in the Lying-in Hospital would not be without interest to this Society.

Sarah Adams, a primipara, aged 20 years, who was then in the eighth month of her pregnancy, was admitted into the Lying-in Hospital on January the 30th, at three o'clock, p.m. I understood from Dr. M'Crea, who brought her to the Hospital that the convulsions had commenced that morning at eight o'clock. When I visited her about half-past three she was in a violent convulsion, her face was pale, greatly distorted, frothing mouth, jerking the limbs. Each attack lasted about two minutes between the seizures, the patient was quite insensible, and there was no interval of consciousness between the fits; the feet and ankles were œdematous, swelled, the countenance heavy and stupid, the pulse quick and weak, she was unable to swallow anything and upon examining the womb I thought I could detect signs of impending labor, although there was no contraction to be felt through the abdominal wall, and the os was not dilated, and the patient exhibited no signs of pain, I had a consultation with Dr. Pirrie, and we agreed to administer chloroform by inhalation, which, for a time, appeared to diminish the frequency and violence of the attacks; we also gave a large stimulating injection which evacuated the bowels; but, although the chloroform was given freely at intervals, the convulsions increased rather than diminished in violence and frequency, but there was no sign of active labour, and the patient's strength was going fast. We decided that the only chance of saving her was by forcibly emptying the womb of its contents. I had noticed that although the os was not appreciably dilated, yet it was not in that rigid unyielding state so common to primiparæ.

Dr. Pirrie kept her well under chloroform, and I gradually introduced my fingers, one after another, within the os, stretched it by separating them and forcing them slowly on, ruptured the membrane, and succeeded in passing the whole hand into the womb, then pushing my hand up to the fundus, I grasped the child's feet and brought them down; but I now found I had another complication to deal with, as the head was Hydrocephalic, and resisted all my efforts to get it out of the womb; I had then to perforate, and the patient was delivered without further trouble. After delivery there was very little hæmorrhage, and no more convulsions.

January 31st No more convulsions have occurred since delivery; the patient is still unconscious; have had to use the catheter and draw off about a quart of smoky urine, loaded with albumen; pulse quick and feeble.

February 10th she was able to leave the Hospital, being quite recovered.

The President.—There are no cases possessed of more practical interest, especially to men in charge of public institutions, than cases of convulsions; and I would, therefore, be glad to hear any remarks any of the members may have on those cases. I am sure few of us who have been connected with public institutions but have had experience of them.

Dr. John Moore.—You have stated that puerperal convulsions are a frightful complication in labour, and more particularly in public institutions. I think they are even more frightful when they occur in private practice. I have seen a good number of these cases. I have about ten before my mind at present, and I believe that though so frightful, they are not fatal. Out of the ten cases only one patient died. Dr. Smyth states this occurred at the 8th month of pregnancy, and that apparently the convulsions were the first symptoms of the case. He has given us a description of the successful termination of a difficult case he treated; but I do not think this one exception breaks through the rule. I found the efforts to induce labour were so irritating to the patient that they only increased the convulsions, and when I had been foiled in my efforts to induce it and desisted, I have found the patient come through. That is one of the points to which I would ask the Society's attention; viz. that, so far as my experience goes, though this was a successful case, it is an exceptional one; and where there is no dilation of the os, and no symptoms of commencing labour, I think the plan is to treat the patient simply for an attack of convulsions, and wait for labour to come on. If labour has come, it is your business to hasten it, and I think from the description we have had here from Dr. M'Meehan, as to the induction of premature labour, Barnes' dilators might be very serviceable in such cases. The only other point is, in regard to the question of bleeding, which is one of the things in regard to which there has been a greater revolution in the mode of treatment than in regard to any other point. We have, I think, abandoned the lancet too much in the treatment of puerperal convulsions. The last time I performed that operation in a case of puerperal convulsions, I resorted to it through the persuasion of an older practitioner than myself, and certainly from the moment the patient was bled, a change came over her countenance, and a modification of the convulsions followed, and she made a good recovery. I think the lancet should not be abandoned, if other symptoms would indicate the necessity for resorting to it—as in the case of a full plethoric per-

son. I can only express my thanks to Dr. Smyth for the interesting paper he has given us.

Dr. Croker.—I have met with several cases of these puerperal convulsions, and formerly the invariable treatment was bleeding. In the Dublin Lying-in-hospital, many years ago, it was the constant resort, but now-a-days bleeding does not seem to be so frequently used. In some of the cases that came under my notice, I found purgatives, such as croton oil, useful. I may say that I listened to the paper with great interest.

The President.—Dr. Croker, have you any experience of emptying the uterus by the dilatation of the os?

Dr. Croker.—Yes. I have been present when several cases of that sort were treated, where the membranes were separated, and a small catheter introduced to bring on irritation of the womb.

Dr. M'Crea.—I saw this case before coming into the hospital. I am inclined to think that labour had commenced. I think I detected a difference in the state of the os in two of my examinations. Another interesting point is, that the woman had anasarca for two or three weeks before the convulsions came on. At the time I saw this case, I thought it a very formidable one, and I think Dr. Smyth and Dr. Pirie deserve credit for pulling her through, as convulsions are very dangerous at this stage.

I would say this is rather an argument against Dr. Moore's idea that we should not bring on labour where we have the convulsions. I think public feeling in this country, as well as of the profession, has undergone some change since Dr. Richardson's celebrated paper on blood-letting—we are more in favour of it than formerly.

I saw in a French Journal statistics given of papers treated in different methods. Formerly the treatment which gave the best results was general blood-letting; and the most unsuccessful treatment of all was chloroform; an equally unsuccessful mode being revulsion.

Dr. Moore was singularly successful in his cases; for it appears by the *Journal*, that, out of 300 tabulated cases, there was a mortality of 40 per cent.

The President.—Does it take any notice of emptying the uterus?

Dr. M'Crea.—It does not. From all I have read of the experience of other people, I would rather be disposed to use Barnes' dilator, than to get the uterus evacuated.

Dr. John Moore.—That takes twelve hours.

Dr. M'Crea.—He says you can put your means in operation for induction of labour, and come back in twelve hours, when labour would be on.

But I would suggest the dilation of the os at once, and even introduce the hand. The treatment of puerperal convulsions, as I understand, would be a dilation

of the os by Barnes dilator at once, and then an operation.

The only rational pathology of the disease we have, is that it is pressure on the renal vein that produces the mischief; and, if so, why not remove that pressure? If that be the theory, it is surely rational to get rid of this pressure as soon as possible, and when that is done, you have only to contend with the already vitiated state of the blood.

Dr. John Moore.—There is much that might be said on the other side of the question. In the first place, I do not think it is pressure on the renal vein, for there are other things that press on it, and no convulsions result.

Dr. Browne.—In one of the old numbers of the Transactions of the Society, there is an account of a case of puerperal convulsions, treated by Dr. Corry. He used chloroform first, and afterwards bled the woman twice within 8 or 12 hours, and with a happy result. This case is recorded in the Transactions of 1860.

The President.—I have seen cases where the exhibition of the chloroform seemed certainly to control them.

Dr. John Moore.—Always, as far as I have seen. Chloral also would control them.

The President.—There are many points of interest before us in the paper, and one I was not aware of before. He states that the mortality is in proportion to the early stage of pregnancy at which the convulsions occur.

Dr. M'Crea.—You will see it in Cazaux.

The President.—Looking on the convulsions in puerperal, as an eccentric matter, I think on the whole they would be less likely to be benefitted by bleeding.

Dr. M'Crea.—But is it eccentric? Is it not from the fouling of the blood by the urea?

Dr. Brice Smyth.—In some cases, blood-letting might be of use, but in the cases I referred to the patients were poor, pale, dejected, worn down people. The bromide of ammonium is considered very good.

The President.—If we go in for blood-letting for puerperal convulsions, why not in cases of convulsions after scarlatina?

Dr. M'Crea.—Richardson recommends it. He speaks highly of blood letting in all cases of uremic poisoning.

Mr. Spedding.—Had the temperature been taken in any of the cases of puerperal convulsions? It was well-known that in cases of uremic poisoning the temperature was low.

The President.—That suggestion is very important. There is still a fine field in these cases of puerperal convulsions open for investigation in regard to some specific and determined line of practice.

The meeting adjourned.

The Eleventh Meeting of the Society was held on the 15th of March, in the Rooms, at the General Hospital. The President in the chair.

Members present Drs. Stewart, H. S. Purdon, Charles, McCrea, John Moore, Bolton, Messrs. Garde, Gribbin and Spedding.

The Secretary reported the death of Dr. Murray, a member of the Society, during the week and stated that in accordance with the custom in such cases he had issued a circular to the members requesting them to attend the funeral which took place this forenoon.

It was then moved by Dr. Stewart and seconded by Dr. Gribbin and passed unanimously that the Secretary be instructed to write a letter of condolence from the Society to the widow of Dr. Murray.

On the motion of Dr. Purdon, seconded by Dr. Stewart, Dr. M'Keown was elected a Member of the Council in the room of Dr. Hill, who has removed to England.

Dr. Corry was elected a Member of the Society.

The President showed an interesting specimen of an after-birth. The woman gave birth to a blighted fœtus which had attained four and a half months, and afterwards in ten hours she gave birth to a full grown child. The placentæ of both children were continuous, except that a portion of one placenta was degenerated and decomposed. The labour was favourable, and the patient was going on well.

He had brought the after-birth for examination as he considered it presented some features of interest. Though there were two bags of membranes, there was only one after-birth. The after-birth of the blighted fœtus became continuous with the after-birth of the full grown child. One portion of the after-birth was completely degenerated and decomposed. So far as his experience went, the case was an exceptional one, though he believed there were cases of the kind on record.

He then exhibited the specimen and explained that the one placenta ran into the other. He asked the woman if she was conscious of any change, and she said that from about the fourth or fifth month her health was not good; and she had abdominal pains over the uterus; but there was no hæmorrhage at the fifth month. This was her third confinement, she being a married woman.

Dr. John Moore said there was nothing new under the sun, and pointed to a cast of three children at one birth whose case had been brought before the Society many years ago by Dr. Bryce, who was present at the birth. It would be seen from the history of the birth of those triplets, which was preserved in their records, that they had gone through somewhat similar stages to these referred to by the chairman in the present case.

The President.—They perished at different periods?

Dr. John Moore.—Yes; there was arrest of development.

The President.—In this case there was evidence that the conception took place at the same time, because there is only one after-birth.

Dr. John Moore.—In some cases there is only one bag of membranes. There could have been only one bag of membranes in the case of the Siamese Twins and the Double-headed Nightingale. Sometimes the placentæ are separate, and lead to rather inconvenient mistakes with medical men. When a placenta follows the birth of a child, medical men sometimes take for granted that the labour has terminated; and it is not pleasant to be called back to finish one's work, as has sometimes been the case where the doctor has been misled by the after-birth, and has failed to detect a second child in the uterus.

Mr. Gribbin said that some years ago a case happened in Eliza Court, off Eliza Street. He had been told there had been a mid-wife in attendance. The child had presented buttocks, and a child was born dead. The placenta came away. He made an examination; and found the os completely closed, but detected as he believed the head of another child. In 72 hours after the birth of the first child, a messenger came for him; and on going he found the patient very ill. Another child came away, head foremost, living and well. The mother, who was a waterman's wife residing in Eliza Court, was still alive and well.

The President said that was an exceptional case. The first afterbirth was completely separate from the other.

Mr. Gribbin.—Yes. That is liable to lead a man to a mistake, if he does not carefully examine the abdomen, it is very easy for the medical man to fail to detect a second child, if it is small; and if the woman has a large abdomen. I recollect another case in Corporation Square, or rather Tomb Street A child was born, and in some hours afterwards the medical man was sent for again, and another child was born. I attended the same woman afterwards. The birth of one child was all right, but in the course of half-an-hour another came. They were both full grown, and had come to the full time.

The President remarked that, in the case exhibited by him, there could arise no dispute in reference to conception, for conception must have taken place at the same time, owing to there being only one after-birth.

Dr. Charles read notes of the following:—

Diastasis, or separation of the epiphyses of the acromion and coracoid processes of the scapula. The first specimen I exhibit is a left scapula and a portion of the left clavicle, which were taken from the body of a female, aged 77. The outer end of the acromion process is separated from the rest of the scapula by an oblique line, more than an inch behind the apex; it

is drawn inwards and forwards, but its connections with the clavicle are still intact. The coracoid process also appears to be obliquely broken across within half an inch of its root. The union between the fragments of both processes is simply fibrous. I may add that I could learn very little concerning the history of the case.

With regard to the true nature of this specimen, two theories may reasonably be maintained. One of these is that fracture of the acromion and coracoid processes has occurred; and the other, that the epiphyses of these processes have been separated by violence from the rest of the scapula, or have never been united to it by bone. In favour of the first view it may be stated that the separate pieces are larger than we usually find the epiphyses of these processes. However, on the other hand it may be urged:—

1. That fracture of these processes is extremely rare;
2. That there is no history of fracture, though the history, it must be admitted, is very defective; and
3. That diastasis or epiphyseal separation is more likely to have taken place, since both processes are involved.

Dr. Hamilton, of New York, whose treatise is probably the best work on fractures extant, states that “there is some reason to believe that a true fracture of the acromion process is much more rare than surgeons have supposed, and that in a considerable number of cases reported there was merely a separation of the epiphyses; the bony union never having been completed. If such fractures or separations occurred only in children, very little doubt might remain as to the general character of the accident; but the specimens which I have found in the museums, and the cases reported in books, have been mostly from adults. It is more difficult, therefore, to suppose them to be examples of separation of epiphyses, but I am inclined to think that in a majority of instances such has been the fact.”¹

Sir W. Fergusson coincides with Dr. Hamilton. He remarks that “the acromion process may be broken, but the accident is of rare occurrence.” He further says “I have dissected a number of examples of apparent fractures of the end of this process, but in such instances it is doubtful if the moveable portion had ever been fixed to the rest of the bone.”²

It cannot then be positively affirmed whether we have in the specimen before us fracture or diastasis of the acromion and coracoid processes; though, in my opinion, the weight of evidence is decidedly in favour of the latter hypothesis. If the view be adopted that these processes were fractured, we must undoubtedly, I think ascribe the cause to direct violence, such

as the passage of the wheel of a cart over the shoulder, or a severe blow or fall upon it,

Dr. John Moore mentioned a case which had come under his observation. A man was pitched from a horse, and there was some dislocation of the shoulder-joint. He found it easy enough to replace the dislocation, but the difficulty was to keep it in its place.

Dr. M’Crea.—As to the case referred to by Dr. Charles, I can hardly understand how the fragments would have been kept so exactly in their place, if it had been a case of fracture. The apposition appears to have been almost perfect.

Mr. Gribbin said he knew a person in his locality in whose case the head of the bone jumped out occasionally.

Mr. Spedding believed that the case mentioned by Dr. Charles was not a fracture.

Dr. Charles read the following notes:—

Vas aberrans joining the ulnar artery. This specimen is interesting more in an anatomical than a surgical point of view. It is a very rare variety of vas aberrans, which was discovered last month in the Anatomical Rooms of the Queens College, during the dissection of the body of a female, aged 30 years. In the arm (right) you will observe that a slender artery, five inches and a half long, arises from the brachial, a little below the middle of the humerus, and two inches below the lower border of the teres major muscle, and accompanies the brachial on its inner side to the neck of the radius, where it joins the ulnar a quarter of an inch from its origin. It is pervious throughout, being with injection like the brachial, but it gives off no branches. The brachial, radial, and ulnar arteries are normal as to their position and number of branches, except that the anastomotic, which should arise from the brachial, is absent.

In the left upper extremity the arteries had a normal arrangement.

Quain, even in his large experience, speaks of having met with only nine instances of *vasa aberrantia*; and those all ended in the radial except one, which joined the radial recurrent; but it was in that case a branch of the ulnar. He states, however, that Monro and Meckel had each observed a single instance in which the *vas aberrans* terminated in the ulnar directly.¹ Cruveilhier has, on occasions, seen a *vas aberrans* joining the ulnar.²

Dr. Charles further remarked that, as far as he knew, there were only four instances recorded of a *vas aberrans* joining the ulnar.

The President.—It is possible that might cause a complication in case of an operation.

Dr. John Moore.—An additional ligature would answer.

¹ A Practical Treatise on Fractures and Dislocations, p. 208, 4th ed., 1871,

² Traité D’Anatomie Descriptive, 4th edition, Tome 3, p. 131, 1871.

The President.—You might possibly take up the wrong artery.

Dr. Charles also read the following notes:—¹

VAS ABERRANS JOINING THE RADIAL ARTERY.

In the left upper extremity I exhibit the radial arises from the inner side of the brachial about two inches above the elbow, crosses the brachial (or ulnar-interosseous) immediately below the elbow, and lies superficial to the pronator radii teres as far as its insertion; but from this point it takes its normal course. Arising from the brachial, half an inch below the lower border of the teres major is a slender vessel, a *vas aberrans*, which is four inches and a half long; it lies on the inner side of the brachial and joins the radial one inch below its origin in the arm.

HIGH ORIGIN OF THE RADIAL ARTERY.

It is a curious coincidence that there were lately, at the same time, in the Queen's College Anatomical Rooms, five upper extremities in which the radial had a high origin; two of these I exhibit. In the first, a right upper extremity, the radial arises from the inner side of the brachial trunk at the insertion of the coraco-brachialis, and accompanies the brachial (ulnar-interosseous) to the elbow, where it crosses to the outside of that vessel. It is then placed superficial to the pronator radii teres, and assumes its normal position in the lower half of the forearm.

In the second—also a right upper extremity—the radial takes origin from the inner side of the axillary close to the head of the humerus, crosses the brachial about the middle of the arm, and then lies superficial to the pronator radii teres till it reaches the middle of the forearm, from which point it maintains its usual relations. In one of the other three arms the radial arose from the brachial at the same place as in the first arm I have exhibited; but it passed between the two heads of origin of the pronator radii teres, instead of over them.

Quain accounts for such cases by supposing a *vas aberrans* to have originated in the arm and afterwards to have joined one of the arteries of the forearm below its origin from the brachial at the bend of the elbow. The sequence of changes which occur during the development of a high origin of the radial, for instance, appears to be the following:—The artery arises from the brachial at the usual place—over the neck of the radius—but at an early period, from some unknown cause, it becomes obstructed for a short distance below its origin. A *vas aberrans* then grows downwards from the axillary or brachial and terminates in the radial below the point of obstruction. At this stage the radial possesses two roots; the upper, which takes origin from the main artery of the limb usually in the middle or upper third of the arm; and the lower, which is connected with the inferior end of

the brachial, and transmits very little blood. Subsequently the obstructed portion of the radial, that is, its inferior root, becomes obliterated, and eventually disappears entirely, so that in the adult, the radial seems to arise directly from the brachial above the elbow.

It will be remarked that altogether I have referred to six instances of abnormal arrangement of the arteries of the upper extremity which occurred in five bodies. One was a case of *vas aberrans* in the right arm; the remaining five were cases of high origin of the radial—four in the right, and one in the left arm. In only one body was the disposition of vessels abnormal in both arms, and in that body, on the right side, the radial arose from the axillary; and, on the left, from the lower third of the brachial, but it was afterwards joined by a *vas aberrans* an inch below its origin. This disposition of arteries in the arms supports the view of Bichat and Quain in opposition to Meckel, who held that “lateral symmetry, the most powerful of all (kinds of symmetry) is maintained even in malformations.”¹

The existence of two large arteries occasionally in the lower part of the arm, either from the high origin of the radial, ulnar, or interosseous, or from the presence of a *vas aberrans*, should be carefully borne in mind by the surgeon who, for any purpose, requires to ligature the brachial. The safe, practical rule to be followed in all such cases is: 1st., that if after ligaturing the brachial, another large vessel can be felt pulsating beside it, a second ligature should at once be applied; and, 2nd., that to stop hæmorrhage in the forearm or hand, the wound should be enlarged and the bleeding ends of the vessel ligatured, else, though the brachial be ligatured, blood may be still conveyed to the wound through one of the arteries of the forearm, arising abnormally from the brachial or axillary above the point of ligature.²

EXOSTOSES OF THE OUTER EXTREMITY
OF THE CLAVICLE.

Two specimens. Clavicle (right) No. 1, was taken from the body of an aged male. On the anterior margin of its outer end there is an irregular bony growth, one inch and a half from side to side, and half an inch from before backwards. It projects forwards and slightly downwards into the substance of the deltoid. Clavicle (left) No. 2, belonged to an aged female. It presents a slender osseous growth, whose root, about half an inch wide, is joined to the anterior margin of the bone nearly an inch from its outer end. This growth is more than an inch long, and is very much curved outwards and slightly backwards and upwards, so that it almost touches the acromion process of the scapula. I think we may regard both bony tumours,

¹ [Two more are described on page 1228 et seq.]

¹ Quoted by Quain in his *Anatomy of the Arteries of the Human Body*, page 265.

² A Description of some of these Abnormalities also given in the *Journal of Anatomy and Physiology*; June, 1873.

more particularly the former, as ossifications of some of the fibres of the deltoid which arise from the clavicle.

The practical point in connexion with these growths is that the surgeon is liable to mistake them during life for the ends of a broken clavicle or for the callus of an old fracture. Indeed, in the dead body, before the soft parts were removed, there was some difficulty in diagnosing the growths on one of these clavicles. However, careful examination of the upper surface of the clavicle, as well as the history of the case, renders it sufficiently easy to tell the difference.

CALCAREOUS DEGENERATION OF THE ARTERIES OF THE BACK OF THE LEG.

The posterior tibial and peroneal arteries which I exhibit were taken from the body of a man, 74 years of age. They are rigid tubes almost from their origin to their termination. The calcareous deposit, though originally confined, according to Rokitansky,¹ to a new layer which lined the vessels, has now encroached to such an extent on all the arterial coats, that they form merely a thin and incomplete covering for the calcareous tubes. Lining the interior of the vessels is a soft cellular layer, which sends irregular projections into the bore of the tubes, and these have served in some places, no doubt, as points of attachment clots of blood. As might be expected, the arteries contain scarcely any injection; indeed in some parts they are almost impervious. From this we can understand how imperfect in such cases must be the supply of blood to the lower extremity, and how liable the feet must be to senile gangrene and low forms of inflammation. The arteries of the other leg were equally and similarly affected.

This is in accordance with the opinion of Sir W. Paget and others,² who believe that calcareous as well as fatty degeneration takes place in corresponding arteries and to the same extent in each. The posterior tibial and peroneal arteries very frequently undergo this variety of degeneration, even when some of the larger arteries are almost free of it. This was the case in the body of the man from whom these vessels were removed; his aorta and iliac arteries being only affected to a slight extent. No doubt calcareous degeneration is very common in the arteries of the aged, and especially in those who have been subjects of the syphilitic poison; but it is seldom one sees arteries more calcified than those before us.

The President asked were there any symptoms of impeded circulation. ?

Dr. Charles.—No. The leg seemed to be fairly nourished for a man of that age. He was 74 years of age.

¹ Manual of Pathological Anatomy, page 267, 1852. Sydenham Society's Edition.

² Manual of Pathological Anatomy, by Drs. Jones and Sieveking, p. 351, 1854.

Dr. Charles then read the following note:—

A REMARKABLE EXTRA-CAPSULAR FRACTURE
OF THE NECK OF THE FEMUR.

This specimen was removed from the body of a male of about 60 years of age. The line of fracture encircles the base of the neck of the femur, passing through the anterior intertrochanteric line in front, and through the bottom of the digital fossa behind; and, as is usual in extra-capsular fracture, the great trochanter is fractured along its line of attachment. The neck of the femur lies horizontally, and is deeply lodged and firmly impacted in the upper end of the femur, so that the force which produced the fracture must have been very considerable. The chief feature of interest, however, in this specimen, is the immense growth of new bone around the base of the neck of the femur, immediately outside the line of fracture. This new bone is composed chiefly of cancellated tissue, and projects, more especially below, in the form of stalactitic processes, somewhat resembling those so commonly met with in chronic rheumatic arthritis. The breadth of the great trochanter from before backwards is more than doubled, so that during life this sign, which was, I believe, first pointed out by Professor Gordon, must of itself have sufficed to establish the existence of extra-capsular fracture.

Dr. Charles said he might add, that they could always diagnose extra fracture by an increased breadth.

The President.—Would not you expect that person would have a shortened limb, but could walk about?

Dr. Charles.—Yes; but the amount of motion was diminished.

The President said he was sure they were all very much obliged to Dr. Charles, for these interesting cases before them. Some of them were interesting in a theoretical and anatomical point of view; while others, especially the last two, were interesting rather in a practical point of view. These cases were well worthy of being placed on record, and would certainly add to the interest of the Transactions.

The meeting then adjourned.

Robert Stewart,
Chairman
22nd March 1873

The Twelfth Meeting of this Society for the Session was held in the General Hospital, on Saturday, March 22nd 1873. Dr. Stewart V.P./the President in the chair.

Members present Drs. McCrea, J. W. Browne, James Moore, Core, David Johnston, John Moore, Whitaker and Mr. Garde and H. M. Johnson.

Minutes of last meeting read and confirmed.

The Secretary read the proof sheets of the reports of the first three meetings of the session which were approved of.

Mr. H. M. Johnson exhibited a small cyst which he had removed from between the eyes of a gentleman. The contents were found to consist of hair.

Dr. McCrea read notes of two cases of hepatic dropsy successfully treated.

Paper:¹ A discussion at the Medical Society of the College of Physicians some months ago directed attention to the diversity of opinion that exists on the value of tapping in hepatic ascites. Recent authors, also, appear to be divided in their views on this subject. Murchison considers the operation a *dernier ressort*, while Habershon and Ward recommend early tapping.

The two following cases (besides presenting other interesting features) have this in common, that in both the operation was performed, and in both the results were favourable.

Case I.—A child, aged three years, was brought to the Belfast Dispensary on December 2, 1872. He was rachitic, and belonged to a very rachitic family. He had been sickly for the greater part of the preceding summer, having lost appetite and become emaciated. When I saw him, the abdomen was distended with fluid; the urine was scanty, and free from albumen; the bowels were regular. On the next day I drew off, by tapping, two quarts of fluid. The liver could now be palpated with facility. It was very much and uniformly enlarged, firm, inelastic, smooth, and not tender. The edge was rounded and free from indentation. After the operation he was ordered a mixture containing iodide of potassium and sweet spirit of nitre guarded by a little carbonate of potash. This he took for three days without perceptible effect, and the fluid was again accumulating. I then prescribed for him eight grains of sal ammoniac every three hours. On December 23rd I drew away three pints of fluid. Shortly before the operation I ascertained that the medicine had not been regularly taken, owing to its unpleasant taste. We found, however, that he took it easily when well diluted. The first few doses had a most marked effect in increasing the quantity of urine. The fluid ceased to form in the peritoneum, and the liver progressively lost bulk. On January 13th the sal ammoniac was dissolved in an iron and chlorate of potash mixture, which was continued for two months. There is now no ascites; the liver appears to be normal; the general health is good; the appetite, before wretched, is now excellent; the face is plump, and the cheeks are rosy. All through the case the hygienic surroundings were bad.

In other respects, besides treatment, this case is interesting. Trousseau (*Syd. Soc. Ed. of Lect.*, Vol. v., p. 56) says of rachitic children:—"Sometimes there is dulness in the lower and lateral parts of the abdomen. This dulness occurs along with fluctuation, and reveals a certain amount of effusion into the peritoneum. Cases of this kind are rare, and a great amount of ascites is

never met with. This is a fact which was noticed by Glisson, by whom none of the symptoms of the disease seem to have been overlooked." And in the next paragraph he points out that real hypertrophy of the liver is an exceptional occurrence in rickets, many of the cases of so-called hypertrophy being merely displacements of the organ downwards. As to the hypertrophy, however, some eminent authorities are against him. Glisson is quoted by Frerichs (*Syd. Soc. Ed. of Frerichs on the Liver*, Vol. ii., p. 175), as having long ago observed, "*Hepar in rachitide laborantibus prægrande est.*" In the same place Bianchi and Portal are given as authorities for a similar statement. What is the exact nature of the liver affection in rickets? Rokitansky speaks of it as lardaceous. Frerichs says that he has seen rickets complicated with waxy liver only once, but with fatty liver frequently. The characteristics described above, as existing in my patient, were not those of fatty liver. Tanner (*Diseases of Infancy and Childhood*, p. 300), says that the enlargement is due to an albuminous or amyloid material. Dickinson, in a paper published in vol. lii. of the *Medico-Chirurgical Transactions*, says that the enlargement of the viscera in rickets is due to a deposit different from amyloid degeneration, and that it bears some analogy to the affection of the bones.

I am not aware that sal ammoniac had been hitherto used for rachitic liven In amyloid liver, Budd tried it successfully, and recommended its use, while Frerichs objected to it and other neutral salts, on the ground of their tendency to start an exhausting diarrhoea and aggravate the cachexia. It is possible to form a plausible theory of its utility if we bear in mind that in contact with an alkaline fluid like blood it will generate free ammonia, and that this will pass through the liver, on which it will exercise its solvent properties before being diluted with the whole mass of the blood. This theory would apply especially to the removal of amyloid deposit, a material which Friedrich and Biermer have shown to be closely related to fibrine; for we have the authority of Richardson (see a paper read before the Med. Soc. of London, November, 11, 1872), for believing that deposited fibrine may be removed by the action of ammonia.

This case also illustrates the diuretic properties of sal ammoniac, which I think are not so generally appreciated as they ought to be. Böcker (quoted in Parkes on the Urine) has shown that it increases all the constituents of the urine. I lately saw its diuretic action powerfully displayed in another case of ascites from enlarged liver in a rachitic child. A large accumulation of fluid was removed in a fortnight, although the medicine was most irregularly administered. The irregularity of administration, however, gave me an opportunity of putting beyond all doubt its diuretic effects on my patient. In this last-mentioned case I cannot appreciate much change in the liver, but I have it still under observation.

¹ [*Dublin Journal of Medical Science*, 1873, v 56, p 109.]

Case II.—A man, aged thirty-five, came to me in May, 1870. There was nothing important in his history. He was slightly jaundiced, and had ascites. His liver was large, firm, tender, and with a regular surface; it was frequently the seat of a dull pain. The urine was scanty, but not otherwise unhealthy. He had a tendency to slight purpuric attacks, which turned up every now and then. Diuretics and purgatives failed to make any impression upon the ascites. We found, however, that broom, digitalis, and iodide of potassium slightly increased the quantity of urine, and that quinine and iron had a good effect on his general health. He lived at the sea-side, and was most carefully nursed. He had a generous diet, with a moderate allowance of sherry. After a progress which I need not detail, the legs and the lower and posterior parts of the lungs became œdematous.

On July 13 I drew away by tapping twenty-seven pints of fluid. The operation was repeated in a fortnight. We finally settled down to a weekly operation. There was one exception to this. At a period when he was free from purpura, I prescribed a pill, containing blue pill, digitalis, and squill. The period for tapping was shortened from seven to five days. After this the weekly operation sufficed. The period for operation was determined by the state of the lower limbs and kidneys. I never waited for distressed breathing to occur. When the lower limbs, which, of course, diminished in size after each operation, refilled as far as the thighs, or where an abrupt diminution of urine occurred, I tapped. The last operation was in the latter part of October. Fifteen operations were performed, and quantities of fluid varying from twenty to twenty-seven pints were drawn off at each operation. When the abdomen was emptied on the last three occasions I observed that the liver was markedly increasing in size. After the fifteenth operation the fluid somewhat abruptly ceased to accumulate. A small quantity was poured out, and remained perceptible for months—even, indeed, after the general health had been restored. The œdema disappeared, and the left lung, which had been dull on percussion from the clavicle to the nipple, cleared up. My patient now, after a lapse of two and a-half years, is robust and energetic, and has digestive powers beyond the common, no food coming amiss to him. The only drawback is that his liver remains large; but as a marked accession of bulk was nearly contemporaneous with improvement, I am the less uneasy on this account.

The following advantages may be claimed for early tapping in hepatic ascites:—

1. It relieves intra-portal pressure. The backward pressure generated in the portal system by hepatic obstruction seeks vent in various directions. In one man diarrhœa, in another bleeding piles, and in another an ulcerated leg relieves the liver. It is unfortunate if the *vis medicatrix naturæ* makes a therapeutical

error, and causes a hæmatemesis. It is not quite so bad if the peritoneum is the safety valve. Tapping unweights this valve, and relieves intra-portal pressure.

2. The removal of the pressure which the effusion exercises on the liver will facilitate the development of collateral circulation through the more healthy parts of the viscus.

3. The relief of the abdominal tension will make it easier for the vena cava, vena azygos, and parietal abdominal veins to establish a collateral circulation between the abdomen and the chest.

4. The removal of tension from the vena portæ and its branches will promote the absorption of remedies.

5. We clear away an impediment in the way of the digestion and absorption of nutriment, which must be seriously affected by abdominal distension.

6. We relieve the kidneys, and these organs are not slow to exhibit signs of relief by increased activity after each tapping.

7. In ordinary cirrhosis we relieve the liver of a pressure that is assisting the morbid processes, which produce contraction.

8. We keep relieved other important organs, the distress of which makes tapping, at least, an absolute necessity.

9. We avoid the danger of typhoid peritonitis, which sometimes attends late tapping.

The doctrine of delay is put by Murchison thus:—"When the ascites has embarrassed the breathing, and not till then, you must draw off the fluid by the operation of paracentesis. The tapping may have to be repeated, but the rule is always to delay it as long as possible, until, in fact, there is danger of the respiratory function becoming seriously interfered with by the pressure of the fluid." The reason which he gives is to avoid the great drain of albumen. And yet, he says, that the operation frequently causes the albumen to disappear from the urine. Surely this is considerable compensation. Besides, as I have already pointed out, the pressure of the fluid cuts off the supply of fresh albumen to the system, by interfering with assimilation. Frerichs puts the same argument for delay in a slightly different shape. He says that the pressure of the ascitic fluid on the vena portæ lessens the rapidity of effusion, and that by paracentesis we give up this advantage. If it be an advantage it is easy to retain it; a tight binder could be used throughout the intervals between the tapplings to keep up the pressure. But would this be judicious? It is noteworthy that in many of the cases recorded by Frerichs, the high pressure generated in the portal system broke out in the gastro-intestinal tract in a flux, which was the immediate cause of death.

In conclusion, the impression left on my mind, both by the cases above-mentioned and by others which were under my observation for short periods only, is, that we may hope for better results in liver dropsy by

Ulster Medical Society
Session 1872–1873
President Henry Martyn Johnston

looking on tapping, not merely as a palliative, but even as a radical method of treatment.

The President said Dr. M'Crea had given some very interesting information in regard to this matter. Their object was to prevent tapping as long as possible.

Dr. M'Crea said the patient was sent by Dr. Stokes, who sentenced him to an early death. He mentioned that he had seen one case in which the fluid had ceased to accumulate after the ninth tapping. That was the only case in which he had seen a good result from tapping. He saw the patient after recovery, and he said the recovery was due to the frequent tapping.

Dr. John Moore said there was a case occurred here, where a second tapping, which was done in the place of the first, wounding the vein of the peritoneum, and eventually hæmorrhage occurred, he would be inclined to go the breadth of the tenura from the former spot.

The President.—Did any of the members present know any case of recovery after tapping?

Dr. John Moore said, yes; one or two. There was a case of a woman who lived in Carnlough. She got perfectly well after he had taken 14 or 15 pints from her.

The President.—How often did you tap her?

Dr. John Moore.—Three times.

Dr. David Johnston said he had one case of Hepatic Dropsy, a little girl of ten years of age, and she got well quickly after a dose of a little scamina and grey powder.

The President.—Had any of the members present any experience of sal-ammonia.

Dr. David Johnston said he had never tried it.

Dr. James Moore said he had listened with great interest to what had been said. He had, like Dr. Stokes, the idea of not going too far. He recollected his father and the late Mr. Wilson having a lady, and they tapped her forty-seven times. She died of another affection. The quantity they took away from her was beyond anything.

Dr. Browne said he recollected reading in the "Journal" relative to the treatment of diseases of the liver by Sal-ammonia. He tried it two or three times in regard to dispensary children, but he never followed it up. It was laid down in all surgeries that they should tap at the same point, and this person was tapped at the same point, and died.

The President said with regard to the enlargement of the liver in children, he did not know whether Dr. M'Crea would regard it as of the same nature. However, his attention had been drawn to it by examining children affected by caries and hip disease. Almost invariably he found, no matter how emaciated, a great enlargement of the liver; and such enlargements had not been attended with dropsical symptoms. But of late, when he had a case of hip disease or caries in children, on examining the liver, he had almost invari-

ably found it enlarged. Of course, this case had been treated by nourishment and iron. He regarded the remarks about Sal-ammonia as useful, and as calculated to draw attention to a medicine which of late had fallen into disrepute; certainly it was more used by the old practitioners than by the modern school.

Dr. M'Crea felt grateful for the flattering way in which the paper had been spoken of. He thought the cases would be interesting ones to bring forward before the Society. In the case in which he tapped fifteen times, he only tapped once on the same spot. He made fifteen distinct wounds, and he thought that what Dr. Moore told them should increase their caution in that respect. As to the number of tapplings that had been performed, they would see in the dissection to which he had referred, a case in which an old woman was tapped ninety times.

After some desultory conversation, the meeting adjourned.

Robert Stewart, Chairman
12th April 1873

The Thirteenth Meeting of the Society was held in the Rooms, in the General Hospital, on Saturday, the 29th March. The President in the chair.

Members present Drs. Stewart, David Johnston, James Moore, John Moore, J. W. Browne, J. J. Charles, Torrens, Spedding, Garde, and Dr. Johnston 78th Highlanders.

Dr. Johnston, of the 78th regiment, exhibited a case of aneurism:—

Lance Corporal_ 32 years of age, 78th Highlanders, who was a musician in the Band, and played, the bass trombone, was about two o'clock in the afternoon of 5th February, 1873, found lying in a latrine, surrounded by a pool of blood, which was coming from his mouth and nose. When brought to Hospital, immediately afterwards, he was dead. He performed his duties to the day of his death, and he had never reported himself sick, and till within a couple of hours of his death he had continued to practice at blowing a wind-instrument; but the washerwoman states she had several times observed his linen to be stained with blood.

Sectio cadaveris, 22 hours after death:

Body.—Fairly nourished, great pallor of lips, periosteal thickening of both tibia, cicatrices of ulcers on penis, induration of separate glands of groin, no sub-occipital induration.

Head.—Not examined.

Thorax.—Old and very extensive adhesion of pleura on both sides.

Both lungs intensely congested, lung substance healthy, pericardium healthy, empty.

Heart.—Some hypertrophy of left ventricle. No valvular disease; an aneurism about the size of an orange, springing from the arch of the aorta, com-

municating by two small openings with the trachea just above its bifurcation. These openings presented a nipple shaped appearance on the internal surface of the trachea. Except a small quantity of clot close to the ulcerations, there were no clots in the vessels or heart. A syphilitic deposit (gummata) studded the aneurismal pouch as well as the entire surface of the aorta.

Abdomen.—Stomach filled with blood; mixed with undigested food.

Dr. Charles said the aneurism was on the first stage of the arch of the aorta. If it had been on the second stage, it would have pressed more on the trachea than it does; it would also have pressed on the thoracic duct, the recurrent laryngeal nerve, and the œsophagus; and the probable result of this would have been inanition, spasm of the laryngeal muscles, and cough, with dysphagia.

Dr. Stewart said it was very remarkable that the man was blowing his wind-instrument a couple of hours before the thing occurred, and yet never experienced any difficulty or distress.

Mr. Spedding observed, that the patient's washer-woman said that there was some blood on his shirt.

The President said they were much obliged to Dr. Johnston for the very interesting case; and the interesting statement that accompanied it. There were many interesting points in connection with it, especially about the man being able to continue his occupation up to the very time of the occurrence, and that he exhibited so few symptoms.

Dr. Johnston, 78th Regiment, said bandsmen were slow to report themselves sick, for they were afraid that the doctor would order them to the ranks; and then they would lose their pay for being bandsmen.

Some conversation regarding some deposits which appeared on the specimens exhibited then took place. Dr. Charles gave the opinion that they were either fatty deposits or syphilitic gummata. He was rather disposed to think they were the latter.

The President exhibited a specimen of a liver, for the purpose of shewing the effects of syphilis in connection with the liver. He said some time ago he had a patient named W_, aged 41, who had laboured under syphilis for nine years. He had never been in health from the time he had the primary sore and secondaries. He lay in the union, suffering from enlargement of the liver, and partial ulcers. He had nodes, one of which suppurated on the cranium. The president then shewed the liver, which appeared to be affected with waxy degeneration. He also exhibited a patient who was suffering from the same form of disease. The patient, he said, had been suffering from syphilis for nine years, and is a shoemaker by trade. He got mercury for the primary symptoms, but not since. He is now suffering from nodes, syphilitic synovitis, and enlargement of the liver. He had another

patient lying up in the wards named J_ L_. He had been suffering from syphilis for five years; at present he had enlarged liver well marked, partial sores, and nodes. These cases are illustrative of the tertiary group.

The other patient of Dr. Johnston was then introduced, and stated that, nine years ago, he got primary sores; and five months ago he got nodes in the head.

The President.—He has also syphilitic synovitis in both knee joints. Had you ever eruption of the skin?

The Patient.—Yes.

The President said there was no dropsy; and what was characteristic of the enlarged liver in syphilis is, it was free from pain, and there was no jaundice. The patient had nearly all the symptoms; he was a man who drank largely, and the only difference between his case and that of L_ was in regard to the time, and the grouping of the symptoms. It was known years since he had a primary sore, and he says he only took mercury for the sore, and that he has never been in health since then; that he had been addicted to drink and dissipation; and that he had eruptions of the skin, sore throat, and about nine months ago a partial croup began to shew itself. He was in Frederick Street Hospital about twelve months suffering from rheumatism, and was noticed in the Journal at that time. He was supposed to be labouring under some affection of the liver, but he did not know the exact thing that was spoken of in regard to it. There were some features of interest in connection with the paper Dr. M'Crea submitted: the absence of ascites, the absence of jaundice, and the freedom from any pain. It also bore the character of amyloid enlargement of the liver. He would give an opportunity next week of discussing L_'s case more fully. The latter was suffering from necrosis of the frontal bones—nodes. He had a liver larger than this produced, no jaundice, no ascites. The case of W_ bore many analogies to those two. Were you ever in Frederick Street hospital except once?

The Patient said, no; that he had been under Mr. Spedding's care frequently.

Mr. Spedding said he was a pensioner and a shoemaker, and he remembered giving him cod-liver oil. Where did you get the mercury?

The Patient.—I got it from Dr. Bell. I was in the regiment of the 4th Hussars,

Mr. Spedding.—Were you abroad?

The Patient.—I was.

The President said he considered these three cases formed an interesting group. W_ was suffering from diarrhœa, which was the immediate cause of death. On post mortem examination, they found enlargement of the liver, and the cuticle and the kidneys diseased, and the tubular portion encroached upon by the disease. The case of L_ exhibited the same symptoms, and he expected to place it before them that day week.

The President asked Dr. Johnston, did he give any mercury in the army ?

Dr. Johnston.—Very little. In our own hospital one doctor gives it another does not,

The President—As a rule?

Dr. Johnston.—I think the majority do not give mercury.

Mr. Guard, to the President.—What treatment did you adopt?

The President said he had adopted giving them a more generous diet than the usual infirmary diet—sweet-milk, and large doses of iodide of potash.

Mr. Spedding remarked that in his experience an enlarged liver was very frequently the sequela of other diseases besides syphilis. He fancied, when they took into consideration the large number of patients that suffered under syphilis, and had no enlarged liver, they could hardly attribute it to the syphilis. He had seen a great many cases of syphilis, and very few cases of enlarged liver. He had at present under his charge the wife of the man L_, to whom the President referred, and she had an immense number of syphilitic convulsions, when she came under his charge.

She was put under a course of iodide of potassium, and she had quite recovered from the convulsions. His wife was a most miserable object; she had nodes in her head; she had got no treatment beforehand—before she came to him—and he gave her large doses of iodide of potassium three times a day, and the convulsions disappeared, and she began taking cod-liver oil.

The President.—Had she any mercury ?

Mr. Spedding.—I think not. She had convulsions twice in twenty-four hours for a month before I was called in, and under large doses of iodide of potassium, after she was slightly iodized, she gave it up, and I gave her cod-liver oil.

Dr. Charles said the case was a most interesting one. With regard to amyloid degeneration of the liver, although it does not always follow syphilis, he thought it was more frequently a sequence of that disease than of any other. Fatty degeneration of the liver is generally believed to accompany or to be associated with scrofulous and tubercular affections.

The President said in cases of syphilis, and of caries, he had not been in the habit of examining the livers of children, but lately he made a habit of examining them, and he discovered enlargement of the liver.

He thought, if physicians made a practice of examining livers in case of syphilis, they would find enlargement more frequently than they did. The President then read an extract in which Berkley Hill said amyloid degeneration is one of the most frequent changes in syphilitic liver, and it is identical with that occurring through the influence of other diatheses.

The parts of the liver so affected, are throughout rather smooth, pale, and semi-translucent, the translucent part turning brown with iodine; but sometimes the hepatic disease attracted little attention during life.

Mr. Spedding.—Do I understand you to say that a large number of children with strumous diseases, and that had not previously had syphilis, are affected with enlargement of the liver.

The President.—Yes; but Dr. Charles remarks that that degeneration is supposed to be of a fatty nature; whereas that resulting from syphilis is supposed to be more of a waxy or amyloid character.

President exhibited a specimen of ulcers of cartilages, with caries of the osseous substance underneath. The patient suffered three years in great pain, and was obliged to get the lump amputated. He was very much reduced; there was complete disorganisation of the structure of the joint, and he suffered a great deal from pains of the limbs. He never saw a man suffer less from general symptoms, since the operation. The President went on to shew that the recovery of patients after an operation in the Union hospital he attributed to the good air there. This patient did not appear to suffer from any scrofulous pain, he was making a good recovery, and gave little trouble.

The Fourteenth Meeting of the Society was held in the Society's Rooms, General Hospital, on Saturday, April 5th. Dr. Stewart V.P./the President in the chair.

Members present Drs. Aickin, Charles, McKeown, James Moore, Corry and John Moore.

Dr. Aickin read the following notes of a case of twin labour, with unusual complications.

The following cases being somewhat curious, and out of the ordinary routine of midwifery practice, I thought them worthy of recording in the annals of this Society.

The first case was that of Mrs. W_, whom I attended in five previous confinements. She informed me about the fourth month of her pregnancy that she would be requiring my services again, and from information she gave, I calculated the time she should be delivered—the 5th November, 1872; as I thought, and now believe, her statements accurate. I consider she carried her pregnancy to the extent of twenty days over the standard time, as she was not taken ill until the 25th; thus making the period of gestation 300 days.

I have notes of her previous pregnancies, to compare the length of time they extended to; and only in the first was there any appearance of extension of time; but I think it may have been a mistake, as the other calculations came very closely, or before the expected time:

1864—November	14;	December	2	+	18	days
1866—July	24;	July	18	—	11	„
1867—December	1;	November	29	—	2	„
1869—January	15;	January	2	—	13	„
1870—September	11;	September	12	+	1	„
1872—November	6;	November	25	+	20	„

On the 24th August (3 months before delivery), I had occasion to call and see her in Hollywood, where she usually spent the summer. I found her in a state of great discomfort and distress, owing to her breathing being very short and oppressed. On examination I found the abdomen very much swollen; in fact, larger than I had ever seen her at full term of pregnancy. Although the limbs and body generally seemed large, it was not the appearance of œdema, but rather of plethora. The veins of the labia were distended, taking bulk of both together, to about size of a large goose egg. On examining per vaginam, which I had to do in semi-erect attitude on account of the breathing, to my great surprise I found the cervix uteri completely obliterated, and the os somewhat dilated, so that I introduced the point of my index finger with ease, and felt the head of child. On again inspecting the abdomen I saw the surface was very smooth and round, with greatly distended skin. Further I could not feel the presence of any part of child, so that, independent of the internal examination, I could have easily mistaken the condition of abdomen as that of ascites. However, it appeared one of rapid accumulation of liquor amnii, but so distended had the uterus become that I told the patient to send for a nurse, and, as it would be likely she would be confined within two or three days, to send for Dr. Dunlop, who would be at hand when she should take ill. Accordingly the next night, the doctor was summoned, as she had regularly recurring pains; but as they were not strong, the doctor left, after remaining an hour or so, and did not see her again. I prescribed her diuretics and purgatives, which acted so well on the swelling that on the 3rd September, ten days after, she was quite relieved; and on the 10th she came to town to be confined under my own care, bringing her nurse with her, believing, as I did, that her delivery might take place at any time, and also considering that we both must have made a great mistake in our calculations. However, a new feature arose which surprised me very much; she remained in town from the 10th to 28th of September, 18 days, during which time I had the opportunity of examining her several times. The uterus, which had been perfectly globular, with neck absorbed, had gradually returned to its more normal state, the os closed, and a neck formed again, measuring at least half-an-inch. From these signs and a general improvement in her other symptoms, I considered it probable she would now go on to her full time, November 5th, and allowed her to return to

Hollywood, from which she again returned on the 6th November, day after calculated time. At *this time*, there was still some neck on uterus. After this I wondered very much at the delay; and on the 23rd found her again in a very weak state, breathing difficult, owing to enormous distention, but this time from presence of something more solid in the abdomen than before. The os was now slightly dilated as before, and I told her she was certainly this time on the verge of confinement. On the second morning after—25th, I was sent for. I was only in the house about an hour when the first child a female, was born without anything unusual happening. Ascertaining the presence of another child, I placed a bandage on her, and after waiting about an hour without pains coming on, I gave a few 15 drop doses of liquor ergot; but with little effect. There was a state of tonic contraction which gave the patient constant pain, but not recurring or increasing like labour. I now thought, after about three hours waiting, that if the liquor amnii, which appeared to distend the abdomen as much as ever, was evacuated, the uterus would act. Accordingly, I proceeded to rupture; but, in trying to do so, I found my finger went through something like straw paper, the membrane not tearing asunder as usual before the rush of waters, but leaving a hole, the size of my finger. This I did not understand, so I carefully examined the protruding watery tumor, as I thought it, again, and pressed the finger further up when I found it passed through something thicker and pulpy; when some fluid began to trickle down; and finding it was blood, I desisted from further interference in that quarter, and examined all over the protruding soft tumour, and came to the conclusion that it was the placenta of the second child attached to the anterior lip of the uterus; but how it was pressed down before the head of the child as a tumor resembling the distended membranes, I cannot well understand. In this condition of things, I thought it wise to have some help, and after some 2 or 3 hours delay, Dr. Pirrie came to my aid, and on consultation, we considered it advisable to deliver at once, by passing the hand up past the placenta and rupturing the membranes behind the child. This was done successfully, and the two feet secured and drawn down. The delivery was finished very speedily; and, in a minute after, two very large and distinct placentæ were expelled along with a lot of coagula, membranes, &c. A mass sufficient to frighten any juvenile practitioner out of his senses. One of the placentæ was a very fine specimen of the battledore variety; the second child, a male, never breathed, and all efforts to assist it were unavailing. After settling our patient, and retiring to another room, Dr. Pirrie said very significantly “that there was a great lot to heal there,” which prediction was too truly verified, as with the shock of the operation, and the very large discharge of the lochia, a thoroughly

anæmic state of the body was produced, ending in sleeplessness, jactitation and puerperal mania, causing death by exhaustion, despite all kinds of stimulation and food, on the 8th December, 13 days after delivery. About the most extraordinary part of the case relates to the weight of the children. The dead child was weighed with a small night-dress, the other with a roller on. The separate weights were: male child, 11½ lbs.; female child, 10¼ lbs., allowing ¾ lbs. for the clothing, and this is ample. The combined weight of the two children amounted to 21 lbs., a weight unexampled, as far as I can ascertain, in the annals of midwifery.

Points of interest:

- 1st. Accumulation of liquor amnii, causing
- 2nd. Obliteration of neck of uterus.
- 3rd. Recurrence of neck on uterus when liquor amnii diminished.
- 4th. Prolonged gestation, of which the history of case leaves little doubt.
- 5th. Position of placenta of second child.
- 6th. Battledore placenta.
- 7th. Extensive surface, off which the two placenta came, leaving little chance of life if mouths of vessels left draining. Each placenta measured something like 9 or 10 inches by 6 inches.
- 8th. Excessive weight of children.

The second case is one of peculiar interest, as it is of very rare occurrence. In the absence of a medical friend I was sent for to attend a lady, on the night of the 4th March last. While waiting back and forward in the room I heard from a relative a very dismal account of the patient's weakness and state of constant debility. For the previous 3 or 4 months she had been living in the country, but owing to her constant vomiting and pain in stomach after eating, persistent from the commencement of her pregnancy, she had come to town to be under the care of her medical friend, whose place I was taking in the emergency. She was treated by him with considerable success, as she obtained marked relief of the urgent symptoms, but some sickness remained to the very last. The condition she was in when first under his treatment was extreme nervous debility, sleeplessness, pain after eating, vomiting almost everything, anæmic, great depression, tongue red, and irritable appearance. Pulse ranging from 100 to 110.

I arrived in the house about eleven o'clock, and on seeing the patient found her as described by relative, very weak and extremely nervous. However, labour proceeded, and after waiting about one and half hour a fine healthy boy was born, which could not have weighed less than 8 or 9 lbs. In the course of 10 or 15 minutes I felt the placenta being nicely expelled, and when through the vulva I twisted it until the membranes were turned out; but I thought some further membranes must be attached to the other side, and

so twisted it again; but as it would not come I introduced my finger gently, in order to make sure of bringing all away at the same time, grasping the contracting uterus in my other hand. Suddenly the membranes, as I thought, became released; but instead of a twisted cord of membranes, I found attached to the end of this an ovum of about six weeks growth, about the size of a large hen egg, and the true cord which I had been twisting (mistaking it for membranes) attached to the same placenta which appeared to have supplied circulation to both. I placed all carefully in an empty chamber, intending to have the specimen for exhibition to the Medical Society; but an hour after (having in the interim gone down to take some refreshment) the nurse told me, when I asked her take care of the specimen for me, that she had already disposed of it, and it was past recovery. I was very sorry, as it was so perfect.

The history of the case is this. The lady was ill with morning sickness and symptoms of pregnancy in the month of May last, and considered herself towards the latter end of the month to be about six weeks pregnant. About this time (25th May) she received a fright, caused by receiving news of the death of a near relative; this was followed by some hæmorrhage, a large amount, lasting only some hours. About a week after she returned home from Belfast (where she had been on a visit) and joined her husband, when she must have become pregnant a second time, the first ovum not being expelled; but remaining with a certain amount of vitality, and acting as an irritant to the uterus all along, as evidenced by the constant and excessive sickness and symptoms almost resembling ulceration of stomach, her great debility and nervousness. Her time of delivery corresponds with the date of hæmorrhage.

Points of interest:

1. Placenta common to both ova, when it was evident there were two distinct conceptions.
2. Persistent sickness, after quickening usually relieved.
3. Ovum not expelled;
4. Or same not causing abortion of self and second ovum.
5. Enough vitality left in ovum not to decay itself, and yet not sufficient to develop ovum.
6. Acting as a foreign body.
7. Child born, being strong and vigorous, and above average notwithstanding mother's bad health, and presence of ovum which might have caused its expulsion at any date.

In reply to the President, Dr. Aickin said he was going to rupture the membranes of the second child; however, in putting his hand through the membranes, his fingers passed through a membrane, as he thought, but it was thin like paper; then, as no water came, he returned and pressed it up again, and his fingers

passed through what he believed to be a second membrane,—that was the placenta of the second child, because the head was right above this membrane and pressing it down in a body.

The President observed that it struck him, it was the placenta of the second child that was passing down. Instead of coming upon the membrane of the second child, he came upon the placenta of the first.

Dr. Aickin said the first child was lying behind, and the back was perfectly free.

The President.—Was there an appearance of a fœtus in the second ovum?

Dr. Aickin.—There was, quite distinct. The second child is still alive.

The President.—When did the birth take place ?

Dr. Aickin.—Two hundred and eighty-one days after. Four days after the hæmorrhage she returned home to her husband, and this occurred two days after.

Dr. M'Keown.—What was the position of the blighted ovum in relation to the placenta ?

Dr. Aickin.—It was a small placenta; and it seemed to be attached to one margin of the placenta.

Dr. M'Keown.—Was there one child.

Dr. Aickin.—Yes; it was twelve inches long.

Dr. M'Keown said it looked as if there were probably two placentæ after all, and that the second had been atrophied.

Dr. Charles observed that this case resembled the one brought before the Society a short time ago by the President. He fancied the two placentæ had been separate at one time, but as they got larger they came in contact, and their vessels interlaced.

The President.—And that there were two distinct conceptions?

Dr. Charles.—I think so, but they were nearly contemporaneous.

Dr. Aickin.—There is no doubt of that, There has been evidence of that in the medical jurisprudence, in which cases are recorded of white and black children being born at the same birth. Of course, they must have been distinct.

The President said he brought a case before the Society some weeks ago, in which there was a patient confined in the Union, and the first child was a blighted fœtus of about five months, and the second child was full grown and lived, and there was one placenta for both. There were two cords attached to the one placenta, and the blighted fœtus was born twelve hours before the full grown child. There was a decomposition of about the fourth section of the placenta.

In reply to Dr. M'Keown, Dr. Aickin said there was no sign of any second placenta. The surface of the placenta was quite even, and presented no injury of any part. There was no line of demarcation between one bit of the placenta and another.

The President (to Dr. Charles)—Would you imagine that, there being a placenta for the first ovum, it should have become attached to the placenta of the new conception?

Dr. Charles.—Yes. The two placentæ might come in contact, and their vessels interlace. I do not say that the vessels anastomosed.

Dr. M'Keown said he believed there had been two conceptions at the same time, and that one of the ovæ became blighted, and there had been two placentæ. On one of the placentæ becoming no more necessary, it atrophied, then the other placenta occupied all the space.

The President said he thought that in the first case where Dr. Aickin introduced his finger to make examination for the second child, he had no doubt come in contact with the placenta of the first slipping down.

CASE OF RUPTURE OF THE VAGINA.

Dr. Corry shewed the uterus and vagina of a woman who had died that morning. Unfortunately he was unable to give a complete history of the case. The deceased had employed a drunken midwife to take charge of her during her confinement. The process of the labour being slow, though the pains it seems were strong, the midwife endeavoured to expedite matters by the administration of ergot and the irritation of the os uteri, &c., with her hand. During one of her manual operations the head of the child disappeared, and the pains subsided. Opium, for some reason was now given, but the labour pains did not return. After waiting for two days from the recession of the head, the friends called him in and wished him to deliver the woman. When he saw her, she was almost *moribund*, and very shortly afterwards died before he had time to make the necessary arrangements prior to instrumental interference. He performed Cæsarean section, and found the child lying free in the peritoneal cavity. He removed the uterus and the greater portion of the vagina.

Dr. Charles, at the request of the members, examined the specimen. The uterus he found firmly contracted and showing no signs of injury externally. The right side of the vagina as well as the peritoneum covering the upper part of it was completely lacerated from the uterus downwards for at least four inches. The edges of the laceration were irregular, softened, and ecchymosed; but the rest of the vagina was tolerably healthy.

The interior was exposed by carrying an incision through the anterior wall in the middle from the fundus of the uterus to the lower end of the vagina. It was now evident that the rupture involved the vagina only—no trace of laceration being detected anywhere in the uterine walls. The interior of the uterus presented the usual appearances observed at this period (12 or 14 hours) after death during parturition. The surface was raw and somewhat uneven, with shreds

of membrane and clots of blood attached. The site of the placenta near the fundus was readily recognizable; and the mouths of the sinuses were seen open and pervious.

Dr. James Moore (to Dr. Corry)—When you passed your fingers up the vagina and found the head of the child, where were the feet and body?

Dr. Corry.—All in the peritoneal cavity. When I opened the abdomen I came upon its buttock. The membranes were all round its body, but the waters had escaped. The rupture must have been very considerable, for the child escaped. The nurse said that just as pain was coming upon her, and the child's head was coming down, the head escaped backwards.

The President.—The os, as far as I can see, seems perfect. There is no injury of the os or of the uterus itself. The laceration likely took place first, and the contraction of the uterus afterwards.

The President (to Dr. Corry)—Had she any children before?

Dr. Corry.—She had six or seven.

The meeting then adjourned.

Robert Stewart, Chairman
12th April 1873

The Fifteenth Meeting of the Society was held in the Society's Rooms, General Hospital, on Saturday, the 12th of April. Dr. Stewart V.P./the President in the chair.

Members present Drs. D. Johnson, Charles, McCrea, Aickin, J. W. Browne, Bolton, John Moore, Messrs. Fagan and Gribbin, Spedding, Garde and Dr. McKewen.

Dr. John Moore exhibited a patient injured by the late collision on the County Down Railway; he suffered then from concussion of the spine, was treated in the hospital, went home, and resumed his work as a carpenter; but he felt that he was not the man he was before, not being able either mentally or physically to apply himself to his work. He was one of those that received the largest compensation, which showed that the doctors were not wrong in their opinion that the injury he received was of a permanent character. There was a want of power in the lower extremity, and a wasting in one of the limbs: he was still improving.

The President exhibited a case of extra-capsular fracture. The patient was in the Union Hospital about a year, and was aged 76. She had the usual signs of extra-capsular fracture; she died of gastroenteritis. She lost her appetite, and then got diarrhoea, which is the general form of death with old bed-ridden people in the Union. He had remarked that extra-capsular fracture gave rise to gastroenteritis, and ended in diarrhoea. The point was, whether the neck of the bone was impacted in the trochanter, or whether bony union had taken place.

Dr. Charles said the line of fracture through the neck was well marked. The great trochanter had been splintered from the neck having been driven into it by the weight of the body, as the thigh came into contact with the ground.

The President said the form of death with old bed-ridden people was general derangement of the stomach and bowels. He attributed it very often to sameness of diet. Another thing he remarked in poor houses, was that these people lived about two years.

The President also showed a case in which he made a *post mortem* examination. The patient was admitted on the first of April, and died on the tenth. When he saw him in the ward, he had not sent for the House Surgeon, which showed he was not suffering from any great uneasiness; but when he examined him he told him he suffered from difficulty in making his water. When examining his abdomen he was amazed at an enormously distended tumour, and he came to the conclusion that it was distended bladder. He seemed not to be suffering any urgent symptoms from such enormous distention. The resident surgeons were of the opinion that it was some form of abdominal tumour. He (the President) drew off an enormous quantity of water perfectly clear. On paying a visit to him last Sunday, he was in bed, and he introduced the silver catheter, and the patient told him he would prefer to keep the water to having it introduced.

He introduced it with great ease; but when he came to the neck of the bladder, he found the usual obstruction to get the catheter over the tumour, and with the introduction of the silver catheter, there came away a considerable quantity of blood. No violence had been used; the water was clear, though some blood came. He got typhoid symptoms, and gradually sank in four or five days. He allowed the urine afterwards to dribble away; and did not interfere with it, and he had continued bleeding. On the day he died, he introduced the gum elastic catheter with considerable ease, and drew off a quantity of bloody urine. He came to the conclusion that, in passing the catheter, he had passed it over some form of cancerous tumour, and that, in using the silver catheter, he had hurt the bladder or tumour, which gave rise to irritation. When he made the *post mortem* examination, he did not open the bladder; but the outside appearance would go to sustain the opinion he held, because he found enlarged glands through the whole pelvis. The case was very interesting. He believed that, if he had let the man alone, he might have lived longer. He remembered a similar case where a private patient was affected with what he believed to be cancer in the lower part of the bowels. His bowels were becoming distended, and they were anxious to have an evacuation. He gave the patient an enema, but immediately after it the patient suffered a shock,

which he showed was owing to the injection going into the cancerous mass which brought on death in twenty-four hours. He thought from these experiences, if the patients were let alone, they would be better.

Dr. Charles.—Perhaps the rectum had been softened by disease and the injection went into the peritoneal cavity.

The President said the water was perfectly clear before the introduction; but, after the introduction of the silver catheter, blood came.

Mr. Gribbin thought that the President had acted perfectly right in the matter. It was his duty to find out what was the matter, and do what he could, and, if bad consequences resulted, he was not to blame.

Dr. M'Crea thought that at the time the doctor used the catheter the disease might have been in a very advanced condition. He asked, was the dribbling relieving the bladder?

The President.—It was. He had gone on for a month with that dribbling.

The bladder was then shown to the meeting.

Dr. John Moore said he quite agreed that it would be right in these cases to leave the patient with distended bladder; however, should absolute retention take place, they would hardly have time to reach him until there would be a rupture of the bladder, it was a most interesting case.

Dr. David Johnston mentioned a case of a man about fifty years of age, from whom he drew three quarts, of water; he had an enlarged prostate. He (Dr. Johnston) was not in his house for a week, and during that time no water passed. The man took an attack of diarrhoea, and he took off the same quantity of water, but a very violent attack of cystitis set in. He had seen several cases of this kind.

Dr. Charles thought the President was quite right in using the catheter. He thought it would be right in such cases not to take away all the urine at once when there was such a large quantity in the bladder; and, by this means, they might avoid cystitis following.

Dr. M'Crea said there was a possible explanation of cystitis coming on after the relief of the bladder. Pressure would prevent congestion, and he thought pressure of the urine would prevent it as long as it was there. There was one point in connection with leaving water in the bladder; very often they were leaving ammoniacal urine; where it had time to become ammoniacal, they should draw it off.

Dr. John Moore thought that where they had that enormous distention, it was certain to produce cystitis; but gradual withdrawing of urine, and letting it down by degrees, was worthy of consideration.

Dr. Charles was requested by the President to make a special examination of the parts. The following is his report:—

The prostate gland is very much hypertrophied, though the "middle lobe" of some anatomists is not prominent. The urinary bladder is enormously enlarged and contains about half a pint of bloody urine with clots of blood; its walls also are thickened, and the mucous membrane inflamed, more especially in the neighbourhood of the neck of the organ. The ureters as well as the pelves of both kidneys are greatly distended; and the kidneys themselves as a consequence are enlarged, pale, and flabby, though the secreting tissue of these organs is nearly normal in size and quality.

The urine contained in the ureters and pelves of the kidneys is of a healthy color. It may be added that the penis is about twelve inches long, that Cowper's glands are three or four times the average size, and that the vesiculæ seminales are large and of a hard consistence.

FEES.

Dr. Aickin called attention to the fee paid to medical witnesses at the Assizes. It was only one guinea. He thought one guinea was far too little.

The President said that the case was deserving of consideration. If Dr. Murney was there, he could give some information on the point. There was a ruling made that, if the practitioner lived in town, he could only receive a guinea a day.

Some conversation took place about this matter, and it was considered desirable that steps should be taken with a view to getting the fees increased.

The President proposed Dr. Thornley as a member of the society.

The meeting then adjourned.

Robert Stewart, Chairman
19th April 1873

The Sixteenth Meeting of the Society was held in the Society's Rooms, General Hospital, on Saturday, the 19th of April. The President in the chair.

Members present Drs. Stewart, H.S. Purdon, Charles, Scott, McKeown, Dr. D. Johnston, Cuming, Wales, Spedding, John Moore and Dr. Johnston 78th Highlanders.

Dr. Thornley was unanimously elected a member of the Society.

Dr. Charles exhibited, on behalf of the President, dissected specimens of (1) the urinary organs of the man whose case had been discussed at last meeting; (2) a polypus of the uterus, with pelvic abscess, and (3) a ruptured male urethra.

The President said that the first was a case which he had explained last week. He had made a *post mortem* examination of the man into whom (it would be recollected) he had introduced the silver catheter, and whose bladder was so much distended. On opening the bladder he found evidences of cystitis, as shown by the injection of the mucous membrane of

the bladder, and the bladder was filled with coagulated venous blood.

Dr. Purdon remarked that with regard to chronic cystitis there was a new treatment which had been adopted. It had been found, where the urine was very ammoniacal, and the ordinary known remedies had failed, that the best results had been found from injecting the diseased bladder with healthy urine; which, it was said, had a beneficial effect upon the diseased mucous membrane of the diseased bladder.

Dr. Wales did not think that the President did any harm in introducing the catheter, and he did not think they would be justified in assuming, from what had happened in this case, that the introduction of the catheter in such cases is injurious.

Dr. John Moore differed from some of the members. The cause of cystitis was great distention of the bladder, and if they allowed it to go on they were only allowing it to go on towards a fatal termination. As to the question of withdrawing the entire water from the bladder, or leaving some of it, it was one that needed some consideration. He thought there was something in the point of gradually withdrawing the fluid; at least, in emptying the bladder partially, and letting it down by degrees.

Dr. Charles adhered to the opinion he expressed last week, that the President was justified in using the catheter.

President.—You would not approve of allowing the water to dribble away?

Dr. Charles.—No.

Dr. Stewart thought it would have been a dereliction of the President's duty as a professional man if he had not taken the course he did.

Other members expressed a similar opinion.

Dr. Charles read notes of the President's second case, a polypus of the uterus, associated with pelvic abscess.¹ He said:—

The uterus is larger than an adult unimpregnated uterus, being four inches and a half long, and two inches and three quarters broad near the fundus. Attached to the inner surface of the fundus, and growing downwards, is a round rod-like polypus, two inches and a half long and about an inch in diameter. The polypus is composed principally of muscular tissue, and covered by the mucous membrane of the uterus. Its lower extremity projects between the lips of the os uteri and is softened, irregular and slightly decomposed. On carefully tracing the Fallopian tubes from the uterus, the ovaries are found firmly adherent to the sides of the uterus and very much altered in appearance. The left ovary lies nearer the vagina than the right, and is made up of a number of cysts which communicate freely with one another. The right ovary is only slightly affected. On the right side of the

uterus and running downwards below the ovary, and by the side of the upper end of the vagina is a large pelvic abscess. The large vessels of these organs are seen lying in it. The omentum is very much thickened and adherent to the uterus and ovaries as the result of peritoneal inflammation. From the position of the ovaries one might infer that the pelvic abscess followed the last pregnancy—probably from the use of forceps during parturition.

Dr. Cuming.—It would seem to me, so far as a cursory examination could go, that the structure of the uterus was healthy, and that this muscular growth had been rather a coincidence, and that from some cause pelvic abscess set in; then peritonitis resulted.

Dr. John Moore.—You think there had been no violence, before you saw patient, in any attempt at treatment.

The President.—No.

Dr. John Moore.—You know peritonitis would follow introduction of a tent.

The President.—The third case of which Dr. Charles has given us a dissection, is one from the body of J_ B_. I found it difficult to get any account of his state before, except that he had gone to the Dispensary medical attendant on Saturday. He told him he was labouring under rupture. The catheter was introduced in the Union Infirmary on Sunday evening, and on the following day I saw him in the wards of the Infirmary. I then found gangrene of the central portion of the scrotum, with a great swelling. He had been a man of very dissipated character. His wife was in the asylum, and he was living with a woman of disreputable character, a well-known character—one who was noted for having robbed people. The catheter was introduced, and a quantity of bloody urine was drawn out. The catheter was introduced afterwards into the bladder. We retained it for a few days, and finding the urine was not going through the catheter, but through a ruptured urethra, we drew it out. Urinary fever set in and the patient died, with symptoms of the usual typhoid state. It occurred to me whether he could possibly, in any connection whilst sleeping with this woman, or by any cause of his own, have ruptured the urethra. The cause of the rupture was the obscure feature of the case. I have not been able to ascertain that it was caused by any instrument.

Dr. Wales.—I would be inclined to think it was a mechanical rupture caused by an instrument.

Dr. John Moore.—The case is a very extraordinary one, and I think it is one of three I have seen. I am not able to give an explanation where violent inflammation of the scrotum came on without any known cause. There was a case in the hospital here, where there was apparently a rupture of the urethra in a case of hernia, and when he was admitted into the hospital he presented all the appearance of urinary

¹ Dr. Redfern made a beautiful dissection of this specimen and has had it placed in the College Museum.

inflammation of the penis. The penis was swollen, was in the same condition, and it turned out that it was inflammatory effusion that had taken place. I saw an old medical man die of the same thing. I think there is no laceration in that urethra, and that it was inflammation of the tissues around it, and I think the sloughing state in which the scrotum was, was inflammation raised up by a distended bladder and spreading to the surrounding tissues.

Dr. Johnstone.—You remarked that he had swelling of the scrotum when he went to the dispensary doctor?

President.—Yes; he represented to Dr. Martin that he was suffering from rupture.

Dr. Johnstone.—I think there has been an old hernia before, and that is what he meant.

Dr. D. Johnston.—I would be inclined to think with Dr. Wales that there was a mechanical rupture.

Dr. Wales.—If I understand you, there was not only swelling of the scrotum but discolouration.

President.—Yes; he was in a complete state of gangrene when I saw him.

Dr. Charles.—I think the patient must have been for some time in a bad state of health; and that the rough passage of a catheter along his urethra, which probably had been somewhat softened by disease, gave rise to that laceration or slough.

President.—May I not have lacerated the urethra?

Dr. Charles.—You may.

Dr. Cuming.—Any man that could tell what had not been there from looking at that *post mortem* would be a clever fellow.

The meeting then adjourned.

The Seventeenth Meeting of the Society was held in the Society's Rooms, General Hospital, on Saturday, the 26th of April. The President in the chair.

Members present Drs. Stewart, Murney, McCrea, Charles, McKeown, David Johnston, Croker, James Moore.

Some conversation took place regarding holding monthly meetings during the summer months. It was generally agreed that it would be advisable, to keep up the interest.

Dr. James Moore moved that they continue to meet once a month every first Tuesday, at Eight o'clock, during the summer.

Dr. Stewart seconded the motion, which was passed.

FEES.

Some conversation took place regarding the fees paid to medical officers attending as witnesses at the Assizes. Dr. Murney said this matter was entirely in the hands of the Attorney-General for the time being. The fee he repeatedly received was two guineas. When Mr. Sullivan was Attorney-General he gave instructions to the Crown Solicitors that when a

medical man was to give evidence in his own town he was only to receive one guinea; but that when brought out of his own town for some distance, he was entitled to two guineas. He (Dr. Murney) found it a great hardship in this hospital, where they attended to the people gratuitously, and then attended before the coroner, and were afterwards obliged to attend at the Assizes. He thought one guinea quite too little.

Dr. M'Keown.—It is a great pity we could not refuse to go. We could refuse to make a post mortem examination.

Dr. Murney.—Yes; but then the coroner could bring in another practitioner from outside.

The President.—Two guineas are little enough for "countrymen." Would it be any use to frame a resolution on the point?

Dr. Murney.—Yes, I think it would be very desirable. I think the Attorney-General would be glad to listen to any remonstrance I believe he has entire control of it.

Dr. M'Keown.—You should endeavour to make the fee three guineas for countrymen, and two guineas for townsmen. I don't see why a country practitioner should go and spend a day for less.

Dr. M'Crea.—I frequently got three guineas for it at Downpatrick. The last time I was there I got two guineas and my travelling expenses.

Dr. James Moore.—The Tyrone people gave me five guineas a day. I was there for some days, and got five guineas.

The President, the Secretary, Dr. Aickin, Dr. Murney, Dr. Croker were appointed a committee to bring forward a resolution on the question.

SPINAL INJURY.

Dr. Murney.—On the 25th January last, a young man, twenty-two years of age, a sailor, was admitted to the hospital, suffering from injury to the spine. He had been engaged in furling the jib sail, and fell on the deck. He lit on the level surface of the deck, directly on the spine. He found he was paralysed from the region of the upper part of the chest downwards. He had the use of his arms, and had sensation downwards to the region of the nipples. Below that there was an entire loss of sensation and motion. There was priapism. On nipping him he had no sensation whatever. On making a careful examination of the spine no fracture could be detected; but from the line to which the loss of sensibility extended, it was evident it was somewhere in the upper dorsal region. Respiration was mainly diaphragmatic. On the 28th of January the urine was first noticed to be ammoniacal in character. The passage from the bowels was at all times involuntary, to his death, and he required the regular introduction of the catheter. The urine was drawn off at short intervals; he was under the influence of bi-chloride of mercury in February. At that time a certain degree of hyper-æsthesia was presented, bed-sores

made their appearance on the 3rd of February. On the 8th of February a bed-sore, about a crown piece in size, affected the sacrum. On the 28th of February he had rigor, and he died on the 27th of March. The seat of the fracture was fifth dorsal vertebra, and there was compression of the cord.

(The doctor here exhibited specimen.)

Looking at the spine you will see a certain degree of tension. The length of time the poor fellow lived was the most interesting feature in connection with this case. There was fracture of the laminae.

The President thought there was commonly pain of the spine. He asked was that from the accident?

Dr Murney.—I think from the accident.

Dr. M'Crea.—Is that sharp pain on the fifth?

Dr. Murney.—It is on the fifth.

The President.—Did you see a private case where a publican in town died off much quicker than I thought? He lived only twenty-four hours. We thought he might live for some days. The class of symptoms that you have described in this case are very much the same as in the case I refer to.

Dr. Murney.—The symptoms in that case were not much more marked than in this case. In your patient the man still had marked priapism. He passed no urine from the time of the occurrence previously.

The President.—The man was sitting on a barrel in his public-house, under the influence of drink, and talking with those around him, and he slipped. He complained of being unable to rise. They took him up in a rough manner, took him up stairs, put him in bed, and sent for a doctor. But he was so intoxicated that the doctor could make nothing of him in regard to the injury. That was about ten o'clock at night. At six o'clock in the morning he was considerably recovered, and told the doctor that he had no feeling down below, and said, "I think, doctor, I have no belly on myself." In the evening I saw him about seven o'clock, and at that time there was no evidence whatever of approaching death. Dr. Murney gave a pretty good diagnosis in regard to the possibility of his dying in two or three days. They were making arrangements about his will. When they asked him to sign his will, and he said he would defer it to the morning. They saw the muscles of the face and neck contract, and in a few minutes all was over. That was in one hour and a half from the time I saw him.

Dr. Murney.—I think in that case there must have been effusion of serum pressing the cord, in addition to the compression which resulted from the falling.

The President.—He had perfect feeling in the upper membranes, but complained of intense neuralgic pains shooting down each arm and forearm.

Dr. Murney.—The injury in that case was much higher up than in this.

Dr. M'Crea.—It is not at all improbable that it was effusion of blood that extended up the spinal cord.

The President.—He was speaking sensibly up to eight o'clock and at ten there was a message brought to me that he was dead.

Dr. James Moore.—You say they took him up roughly. Might he not have got severe injury in their so doing—turning and twisting?

The President.—I am sure the way he was taken up must have had an effect on him.

Dr. James Moore.—The reason I say this is, that I had a case which to some extent appears analogous. I was sent for to see Lord Massereene, who insisted on being kept quiet by his attendants. If he had been roughly treated, and allowed himself to be lifted and laid as some of them wanted, he would not have held out as he did.

The President.—How long did he live?

Dr. Moore.—He died on the night of the tenth day.

The President.—Where was he injured?

Dr. Moore.—About the sixth or seventh cervical. He was paralysed from the arms all down; his bowels and bladder refused to act. He somehow had no sensation, though his mind was perfectly clear from the beginning to the end, and he could take his food well.

Dr. Croker.—What was the accident?

Dr. James Moore.—He was on a grassy soft sloping embankment going to bring a yew tree close to a stake that was close by.

In pulling, the tree and the stake gave way together, and he toppled down off the soft grassy bank over a wall, on a walk, where some stones had been laid for making a rockery in her ladyship's ground, the back of his neck came against sharp stones. He was paralysed and his mind was clear for eight days.

Mr. Spedding thought that these cases of spine fracture were most interesting in a practical point of view, as they showed the utter uselessness of the operation of trephining that was often sought on. In all cases the cord was so much injured, cut across or depressed, that often the depressed bone was elevated. He questioned if the operation of trephining had any effect whatever.

Dr. James Moore.—I quite agree with you. To dig down into the spinous process of a bone is a useless work.

Dr. Charles.—Fracture in most of the cases referred to occurred at the most common seat. There is no part where fracture occurs more frequently than at the fourth or fifth dorsal vertebra, and you can understand the cause of that, from the anatomy of the part, the body of the fourth dorsal being the smallest of all the dorsal; hence it is most commonly fractured.

Dr. M'Crea.—I don't see that there can be such an extreme objection to giving a man a chance by trephining. For you cannot know whether the cord is injured or not till you try, and the case is fatal any way.

The President.—Dr. M'Donnell, of Dublin, first introduced trephining, but not with great success, and of late it has fallen into disuse.

The Eighteenth Meeting of the Society was held in their Rooms, on Tuesday evening, May 6th, at eight o'clock, the President in the chair.

The report of the Sanitary Committee was handed in, and a query sheet arranged to be forwarded to the Dispensary Medical Officers and others.

Dr. Murney exhibited a specimen of fracture of spine and read notes of case.

VERY RARE TUMOUR OF THE THYMUS GLAND.

Dr. Charles exhibited a tumour of the thymus gland, which had been removed from the body of a female, aged 15 years. The tumour was of the size and shape of a small orange, and was found lying in the anterior mediastinum on the right side of the pericardium. Dr. Charles had not made an incision into the tumour, as Dr. Redfern intended to examine it microscopically; but he stated his belief that it would prove to be of the nature of the sero-cystic sarcoma of Brodie or of those tumours described by Paget as "cysts proliferous with vascular growths." He referred to cases related by Sir Astley Cooper and Mr. Simon in their Essays on the thymus gland. He thought the tumour exhibited corresponded in most of its characters to the one described by Mr. Simon.

(Merely a general account of this tumour is given here, as Dr. Redfern will probably describe it in detail in one of the Journals.)

CONTUSION OF THE BRAIN BY CONTRE-COUP.

At a subsequent meeting, the President brought forward an interesting case of injury to the brain. A man received a severe blow on the left side of the forehead, and was received into the Union Hospital, suffering from the usual symptoms of so-called concussion of the brain. In a few days he recovered, so as to be able to walk about. But nearly a fortnight after the accident, symptoms of compression of the brain showed themselves, accompanied by several convulsive attacks. He continued to get worse, and sank comatose about three weeks after he met with the injury.

Dr. Charles described the post-mortem appearances. The frontal bone on the left side, near the frontal eminence, presented a well-marked indentation of the outer table as large as a four-penny piece. On the corresponding part of the inner table there was only a slight mark or depression. Directly behind the injured spot of bone the brain was very soft, and presented a small abscess, about the size of a large pea. The remainder of the same hemisphere—more especially the posterior lobe—as well as the whole of the cerebellum, was softened, and showed evident signs of congestion. Over the posterior lobe of the left hemisphere the membranes were inflamed and much

thickened, and in the cavity of the arachnoid there were nearly three ounces of greenish yellow pus. The right hemisphere was normal in appearance; and there was no injury to the skull visible, except that to the frontal bone already described. It will be remarked that the injury to the brain was greatest, not beneath the part struck, but at the point directly opposite to it, on the same side and at the same level. It was clearly, therefore, a contusion of the brain by *contre-coup*.

ADDENDA.

Page 28 {1164}.—The description of the French instrument for reducing dislocations of the thumb, referred to by Dr. Charles, should have been:—It consists of two blades of wood, joined together like those of a pair of scissors, but working in the opposite direction. To each of these is attached a piece of leather, cut transversely, so as to leave narrow slips. By an ingenious contrivance the slips of the two pieces interdigitate in such a manner that the thumb can be inserted between them, and very firmly grasped when the handles have been brought together. With this instrument, a large amount of force can be readily applied to the thumb.

Page 59 {1181}.—Dr. M'Crea's paper on "Tapping in Hepatic Ascites" appeared in the Dublin Monthly Journal of Medical Science, August, 1873, and has not been reprinted in the Transactions of the society.¹

SYNOPSIS

OF THE

BUSINESS OF THE ULSTER MEDICAL SOCIETY,

SESSION 1872–73.

FROM THE NOTICE PAPERS.

First Meeting, Saturday, 16th November, 1872.—The President will exhibit cancerous disease of œsophagus, resulting in rupture of descending aorta; also, diseased prostate and kidneys.—Dr. J. W. T. Smith will exhibit and give notes of a case of aneurism of transverse portion of aorta bursting into trachea.

Second Meeting, Saturday, 30th November, 1872.—Dr. J. W. T. Smith will read notes of a case of aneurism of the aorta causing ulceration of the trachea, and will show the parts.—Dr. Brown will exhibit a case of fractured spine, and give a history of the case.—Dr. M'Meehan will read notes of a case of induced premature labour.—Dr. Spedding will read notes of a case of ligature of Hemorrhoids. He will show a tumour which

¹ [See page 1181 for a transcription of the published paper.]

Ulster Medical Society
Session 1872–1873
President Henry Martyn Johnston

he removed from a patient, and will exhibit an acephalous foetus.—Dr. John Moore will read notes of gunshot and other wounds treated in the General Hospital during the riots in August last.

Third Meeting, Saturday, 14th December, 1872.—Dr. Brown will exhibit a case of fractured spine, and give a history of the case.—Dr. M'Meekin will read notes of a case of induced premature labour.—Dr. Spedding will read notes of a case of ligature of hemorrhoids. He will show a tumour which he removed from a patient, and will exhibit an acephalous foetus.—Dr. John Moore will read notes of gunshot and other wounds treated in the General Hospital during the riots in August last.—The President will exhibit a case of abscess of tibia, and read notes of case.

Fourth Meeting, Saturday, 4th January, 1873.—Dr. H. S. Pardon will introduce a patient suffering from favus.—Dr. Murney will give an account of the post-mortem on the victims of the recent murder at Holywood.—Dr. John Moore will conclude his paper on gunshot and other wounds treated in the General Hospital during the riots in August last.—Dr. Browne will exhibit a diseased wrist joint, for which amputation of hand was performed.—The President will exhibit specimens of abscess of tibia, of hypertrophied heart, and of cancer of stomach.

Fifth Meeting, Saturday, 18th January, 1873.—The President will exhibit specimens of hypertrophied heart, and of cancer of stomach.—Dr. James Moore will exhibit a lacerated hand which he amputated.—Professor Coming will show a case of aortic aneurism, and give history of case.

Sixth Meeting, Saturday, 1st February, 1873.—Recommendation of Council:—"That the Meetings of the Society be held weekly instead of fortnightly, as heretofore."—The President will exhibit several pathological specimens.—Professor Cuming will exhibit a case of aortic aneurism, and read notes of case.—Dr. James Moore will exhibit a case of laceration of elbow, requiring amputation of arm.—Dr. M'Keown will read notes of cases of iridectomy on patients introduced at last Meeting of Society.

Seventh Meeting, Saturday, 15th February, 1873.—To consider the desirability of holding weekly meetings of the Society instead of fortnightly, adjourned from last meeting.—Dr. John Moore will introduce a patient with obliterated brachial artery from wound in axilla; also a case of irreducible dislocation of thumb. He will also exhibit a strumous testis which he excised.—Dr. H. S. Purdon will introduce a patient the subject of Graves's Disease.—Dr. Browne will read notes of a case of peritonitis following the introduction of a tangle tent into the uterus. (The case resembled one of

strangulated hernia, a tumour existing in the groin, which on operation was found to be an obliterated hernial sac.)—The President will exhibit an obliterated hernial sac from a case of obstructed bowels, in which the operation for hernia was performed; also a specimen of post partum pelvic abscess, opening into ilium.—Dr. M'Crea will read notes of cases of idiopathic neuritis.—Brice Smyth, M.B., will read notes of a case of puerperal convulsions.—Dr. Charles will exhibit and describe the following recent specimens:

1. Fracture of the acromion and coracoid processes of the scapula.
2. A *vas aberrans* of the arm
3. A remarkable extra-capsular fracture of neck of femur.
4. Calcified arteries of back of leg.
5. Bony growths on the outer end of the clavicle.

Eighth Meeting, Saturday, 22nd February, 1873.—The business consisted of the reading of papers postponed from previous meeting.

Ninth Meeting, Saturday, 1st March, 1873.—Dr. M'Keown will move—(1) That a Committee, to be called the Sanitary Committee, be appointed to report quarterly to this Society upon the sanitary condition of Belfast. That such reports, and the discussion thereon, be published in the daily papers for the information of the public and of our local boards, and for that purpose that the representatives of the press be admitted.—(2) That such of the Medical Officers of Dispensaries and Charitable Institutions of this town as are members of this Society, shall be ex-officio members of the sanitary committee.—H. S. Purdon will show a patient with "Progressive Muscular Atrophy."—Papers will also be read by the President, by Drs. John Moore, M'Crea, Brice Smyth, and Charles.

Tenth Meeting Saturday, 8th March, 1873.—Dr. M'Keown will move the appointment of a Sanitary Committee, postponed from last meeting.—Dr. Charles will exhibit several recent pathological specimens, and give histories of them.—Brice Smyth, M.B., will read notes of a case of puerperal convulsions.

Eleventh Meeting, Saturday, 15th March, 1873.—Dr. Johnston, 78th Highlanders, will exhibit a case of aortic aneurism, with syphilitic deposit.—The President, Dr. Charles, and Dr. John Moore will also exhibit pathological specimens.—Dr. M'Crea will read notes of two cases of hepatic dropsy successfully treated.

Twelfth Meeting, Saturday, 22nd March, 1873.—Dr. M'Crea will read notes of two cases of hepatic dropsy successfully treated. (Adjourned from last meeting).—Dr. Aickin will read notes of two twin labours with unusual complications.

Thirteenth Meeting, Saturday, 29th March, 1873.—The President will exhibit a diseased knee-joint, for which he performed amputation of thigh,—Dr. John Moore will exhibit an abscess of brain, resulting from concussion.

Fourteenth Meeting, Saturday, 5th April, 1873.—Dr. Murney will show a case of fractured spine, and read notes of it; and also give the particulars of a case of fractured skull, and show the brain.—Dr. M'Keown will read notes of several interesting ophthalmic cases.

Fifteenth Meeting, Saturday, 12th April, 1873.—Dr. Murney will exhibit several pathological specimens.—Dr. Corry will exhibit a ruptured vagina, and give a history of the case.—Dr. John Moore will read notes of a recent visit to the Infirmaries of Edinburgh and Glasgow.—Dr. M'Keown will read notes of a case of tertiary ulceration of throat with treatment.

Sixteenth Meeting, Saturday, 19th April, 1873.—The President will exhibit a specimen of intra-uterine tumour, associated with pelvic abscess.—Also the pathological appearances presented in a fatal case of ruptured urethra with extravasation of urine.

Seventeenth Meeting, Saturday, 26th April, 1873.—Recommendation of Council—"That meetings of the Society be held during the summer on the first Tuesday of each month, at Eight o'clock in the evening."—To receive report of Sanitary Committee.—Dr. Murney will exhibit a case of fractured spine, and give history of case.—Professor Cuming will show a malignant abdominal growth, and give history of case.—Dr. John Moore will exhibit a calculus extracted from the urethra of a boy; also the head and fragments of a humerus of a case in which he performed amputation at the shoulder joint. Will introduce a patient who had compound fracture of skull, with depression; and one with compound dislocation of wrist-joint.

Eighteenth Meeting, Tuesday, 6th May, 1878.—Dr. Charles will exhibit and describe an exceedingly rare tumour—a *cystic sarcoma* of the thymus gland.—Professor Cuming will show a malignant abdominal growth, and give history of case.

Annual meeting 1873 [November?]

Present, H. M. Johnston President in the chair, Drs. Stewart, H. S. Purdon, Brice Smyth, Charles, McKeown, McMeekin, J. W. Browne, Core, Spedding, Garde, J. W. Smith, John Moore and Fagan.

Minutes of last Annual Meeting read and confirmed.

The Secretary read the Annual Report of Council which was ordered to be entered in the minutes of the Society.

The election of office bearers for the ensuing year was then proceeded with.

S. Browne L.K.Q.C.P.I. R.N. was unanimously elected President.¹

Drs. J. W. T. Smith and Murney Vice Presidents

Drs. Charles, McKeown, Brice Smyth, H. S. Purdon, Spedding and McCrea were elected Members of Council;

Dr. John Moore was requested to continue his services as Secretary and Dr. Fagan as Treasurer. Drs. Spedding and Whitaker to act as Auditors.

REPORT OF COUNCIL

The Council has much pleasure in stating that the progress of the Society during the past year has been most satisfactory. The increased interest of the two previous years has not only been maintained but exceeded.

Ten new members have been enrolled; and eighteen meeting of the society held: the meetings were well attended and the papers read, the specimens exhibited, the patients introduced, the cases narrated, together with the discussion following them, were unusually interesting.

The Council regret to have to record the loss of three of its most estimable members, Drs. Thomas Reade, Pierre and Murray.

The former was one of its oldest members and long occupied a most prominent position in the profession in this province. His researches on the effect of the poison of syphilis on nervous tissue were the first to point out that these tissues were not exempt from the ravages of that disease. He had a high social position and was greatly respected.

Dr. Pirrie was cut off in the prime of manhood and in the midst of his labours. His genial, pleasant face will long be missed from the meeting of the Society; a consultant in the department of medicine which he had made his own namely obstetrics. He willingly placed his services at the command of his professional brethren and was ready to accompany them at all times and to all places and often without hope of fee or reward. He was much loved and deeply regretted.

Dr. Murray was an industrious, painstaking and skilful practitioner and had formed a large circle of friends.

The Council look forward with interest to the approaching meeting of the British Association for the Advancement of Science to be held in Belfast in August next and would recommend this Society to

¹ [Although Samuel Browne was elected at the Annual Meeting, subsequent records show John Moore signing the minutes as President. Samuel Browne was not at the Annual Meeting and it seems probable that he refused the position.]

Ulster Medical Society
Session 1872-1873
President Henry Martyn Johnston

make arrangements for providing suitable entertainment for the distinguished members of the profession who will no doubt visit our town at that time.

The appointment of a Sanitary Committee to watch over and report upon the condition of the Town will it is hoped be attended with advantage by not only affording the public some knowledge of sanitary science but by pressing upon the authorities the necessity of attending to conditions which impair the health of the community and increase its death rate.

The council regret the delay that has occurred in the publication of the Transactions which arose from causes beyond their control, but hope that very shortly the complete volume will be in the hands of the members

John Moore, President
4th November 1874

ULSTER MEDICAL SOCIETY

SESSION 1873–74

The First Meeting of the Society was held on Saturday 15th November 1873.

The only members present were Drs. Charles, J. W. Browne and John Moore.

As several students were present Dr. John Moore introduced a patient whose elbow joint he had excised on the 9th July last.

Paper.¹—The patient, a fine healthy-looking lad, aged thirteen years, while following his occupation of attending to a machine in a paper manufactory, had his left elbow caught between a strong projecting pin on a revolving roller and the frame of the machine, whereby the humerus was broken just above the condyles, and the condyles themselves split and comminuted, the external one being partially driven out through a wound about two inches long, situated just over it.

It was evidently a case for operative interference, and excision of the joint was decided on. The patient was placed under the influence of chloroform, and an incision made to the outer side and parallel with the ulnar nerve, which was carefully separated with the surrounding tissues from the internal condyle, and drawn, by means of a retractor, inwards and out of harm's way.

Another incision was now carried across the joint so as to connect the wound made by the accident with the first incision, and thus render the operation the same as that by the old H-shaped incisions. The articulating end of the ulna was cleared and sawn off, leaving the head of the radius intact; the fractured condyles and comminuted portions of bone were easily separated, and the fractured end of the humerus trimmed with the cutting forceps. The wound having been cleared, the edges were drawn together by wire sutures, and the arm placed on an angular splint. The wound healed kindly, and there was very little constitutional disturbance.

He was discharged on the 13th September, with the wound completely healed, with power of flexion to a right angle, and with perfect use of hand and arm. He is now following his former occupation, with but little inconvenience from the injury he suffered.

The Second Meeting of the Society was held on Saturday 29th November.

Dr. McCrea in the chair, members present Drs. Charles, McKeown, Bolton, J. W. Browne and John Moore.

Cases published under the title "Transactions of the Ulster Medical Society" in the Dublin Journal of Medical Science, 1874, v57, p385.

December 1873

Amputation and use of Esmarch's Means of Restraining Hæmorrhage.—The PRESIDENT read notes of the following case:—M. P., aged forty-five, a stout strong man, was engaged on a ladder at his employment as a carpenter, when it slipped, and he fell from a height of more than twenty feet, fracturing the left femur immediately above the knee-joint, separating and splintering the condyles with complete dislocation of the fragments, and a large wound opening into the joint. The case was one demanding immediate amputation, to which the patient readily consented. It was determined to try Esmarch's method of restraining hæmorrhage and an elastic roller was carried from the toes to the upper portion of the thigh, a pad of lint having been previously placed over the wound. Chloroform was then administered, and when the patient was fully under its influence, a band of vulcanized India rubber was carried round the limb, and fastened by hooks attached to each end. The roller was then unwound, and the limb amputated as close to the injured parts as the state of the wound would admit, the bone being sawn through about the junction of the lower with the middle third. There was scarcely a trace of blood to be seen during the formation of the flaps, which were of skin, or the division of the soft parts and separation of the limb. A ligature was placed upon the femoral and the constricting band removed. Two small vessels spouted and required ligature, and there was some regurgitation from the femoral vein, which also had to be tied. Not more than two ounces of blood were lost during the operation. The wound healed by primary adhesion, except at the angles where the ligature lay; the last separated on the fifteenth day; the completion of feeding was effected in three weeks, and the man discharged at the end of four weeks from the receipt of injury.

In this case, though the man was stout, plethoric, and robust, with a thick limb, there was no symptom of local congestion or other evil resulting from pressing back into the circulation the blood contained in his limb, and he had lost none from the accident. A tendency for the edges of the wound to slough has sometimes been supposed to result from the application of the elastic bandage, but in this case the wound healed most kindly, and his progress to recovery was uninterrupted.

Dislocation of Hip-joint Reduced by Flexion and Rotation.—The PRESIDENT stated that on the evening of the 21st November, 1873, he was requested by Dr. Newett to see with him a patient, whose left hip had been dislocated by the upsetting of a cart in which he had been riding home from Belfast. The usual symptoms of that accident were well marked. Reduction was

¹ [Dublin Journal of Medical Science, 1874, v57, p385.]

effected by grasping the ankle firmly and flexing the leg upon the thigh, and then carrying the thigh upwards towards the abdomen, and on rotating the limb outwards it slipped into its place with the greatest ease. The simplicity and facility of this plan of reducing these hitherto troublesome dislocations, and its advantage in this case were so striking as to induce him to bring it under the notice of the members of the Society.

Noma Pudendi.—DR. FAGAN introduced a patient, who was under his care at the Belfast Children's Hospital, suffering from the above. The disease had assumed a malignant form, and was arrested only by the free application of the strong nitric acid.

He remarked that, in his experience of such cases, the only effectual and safe treatment was the immediate application of some powerful caustic, with tonics and stimulants internally. The dressings used were of a stimulating character. The child above exhibited was nearly well, but a drawing represented the disease on admission at its worst stage.

Ulster Medical Society. The Fourth Meeting of the Society was held on Thursday January 1st 1874.

The President (Dr. John Moore) in the chair, members present Drs. Stewart, Charles, J. MacCormac and H. S. Purdon.

Dr. Whitla who was proposed at the last meeting was balloted for and duly elected a member of the Society.

The President remarked that he had been in communication with the Secretary of the British Medical Association with the object of having our Society associated thereto.

Dr. Stuart proposed and Dr. Charles seconded the following resolution "That the British Medical Journal be added to the list of those taken by the society."

A committee consisting of the President, Drs. Stewart, Charles, MacCormac and H. S. Purdon was appointed to make arrangements about the Annual Dinner to meet at Thompson's on Monday 5th inst at 4 o'clock p.m.

The President then read a paper on "A case of labour complicated with abnormal presentation and contracted pelvis."

Paper:¹—The PRESIDENT said:—On Saturday, the 1st November last, I was consulted by Mrs. W. with regard to the propriety of the induction of premature labour. She stated that she was in the eighth month of pregnancy with her fourth child, and gave me the following history of her previous confinements:—

Her first was premature, and the child was dead some time; this labour was, notwithstanding, terminated by the aid of the forceps. Her second confinement was at full term, and she had to be delivered by craniotomy. Her third labour was "induced" at the eighth

month, but even this did not succeed in saving her child, as her delivery had to be accomplished by the forceps, and the child only gave a gasp and expired.

Under such circumstances I arranged to visit her on the following Monday and make a careful examination of the pelvis and inform her what I should advise her to do. She was unwilling to have labour induced, as she suffered more from it than in her previous confinements; she was of low stature and of slender build. Before the hour for my appointed visit on the Monday, I received a message to say that she was ill, and requesting me to call at once. On my arrival I found that labour pains had commenced, so the first problem was solved most satisfactorily, as on examination I found the cavity of the pelvis so contracted, and the promontory of the sacrum so projecting, that the normal space was diminished by more than an inch. I concluded that she was nearly correct with regard to her time, as a considerable portion of the cervix uteri was still undeveloped. The head was found presenting. At one o'clock, three hours after my first visit, some progress had been made, the pains were recurring at regular intervals, and the os was dilated to the size of a crown piece, the membranes still unruptured. The uterus and child still kept high and did not descend into the pelvis. At four o'clock, on calling, I found the patient getting into bed from the night chair on which the membranes had ruptured, and, on making an examination, I found the cord still pulsating lying in the vagina, with a hand and arm projecting beyond the head.

As commencing labour had solved the first problem which the case presented—namely, whether it was one for "induction of premature labour," or whether she should be allowed to go on to the full period of pregnancy, so the second problem was now solved—viz., what method of delivery should be selected. At this stage of the labour, when it was not improbable that craniotomy might have to be resorted to, I requested the assistance of Dr. David Johnston, who kindly aided me. As the uterine contractions were fortunately not violent, I found but little difficulty in the introduction of the hand into the uterus, but considerable difficulty in finding a foot, as the child seemed twisted in a most peculiar manner; having succeeded, however, and bringing one down, the head did not revolve, and there was now in the vagina a hand, a foot, the cord, and the head at the brim. As the foot seemed most inclined to return to the cavity of the uterus, I placed a loop of tape around the ankle which kept it under control. The absence of strong uterine contractions was very favourable for remedying this mal-position, which a little manipulation and perseverance accomplished, and the breech and body were at length brought down and the arms were relieved. The pulsation in the cord was becoming very feeble, though it could still be felt, but all our efforts to get away the head, by any manoeuvring or traction compatible with the life of the

¹ [Dublin Journal of Medical Science, 1874, v57, p385.]

child, failed. I succeeded, however, in extracting it without reducing it, but only to see it make one or two feeble efforts at respiration and then expire. The child was a male, and as large as an average one at the full period.

Dr. J. MacCormac asked if the deformity was in the sacrum.

Dr. Charles gave some interesting facts regarding the different measurements of the pelvis.

The PRESIDENT, in reply, said that the deformity was occasioned by the sacrum, and he thought that the best pelvimeter was the finger.

Dr. H. S. PURDON remarked that Dr. Murphy, of London, in his work on Midwifery, advised the student not to trust to pelvimeters, however ingeniously contrived, and held that time and a close attention to the symptoms which present themselves decide upon the line of treatment to be taken.

John Moore
January 15th 1874

Ulster Medical Society. The Fifth Meeting of the Society during present session was held on January 15th 1874.

The President in the chair. Members present Professor Dill, Drs. Stewart, McCrea, Walton Browne, Fagan, McKeown, Charles, Garde, McConnell, Gribbin and H. S. Purdon.

It was agreed that Drs. McCrea and Fagan be appointed a subcommittee to see if a suitable room could be obtained in a central position for a reading room for the use of members.

Dr. Charles exhibited a specimen of gastric ulcer.

Paper:¹ DR. CHARLES exhibited a very interesting specimen of ulcer of the stomach. The patient, aged fifty, had been in the Union Hospital. The stomach was contracted to about one-third of its original size, and all its coats greatly thickened. A small ulcer was also apparent. He had examined microscopically for cancer, but the result was negative. The heart was also atrophied. Dr. McCrea asked if there was any history of syphilis, or if he had examined for amyloid deposit.

Dr. Fagan thought that there was some peculiar tendency to atrophy generally, as other organs were said to be smaller than normal.

Dr. McKeown held that excessive tea drinking, as well as abuse of alcoholic stimulants, was injurious; indeed he thought the former led to disease of the mucous coat of the stomach much more frequently than the latter.

Dr. H. S. Purdon stated that the prolonged abuse of alcoholic drinks gave rise to a catarrhal state of the stomach in the final instance, followed by a new growth of connective tissue, which finally pressed on and oblit-

erated the follicles, causing an inveterate form of dyspepsia. He also stated that the modes of death from gastric ulcer were generally held to be three in number—by perforation, by opening into a blood vessel, and thus inducing hæmorrhage, and by debility and exhaustion consequent upon the vomiting and non-absorption of food. He held that in cases of gastric ulcer sugar was very injurious, and that cancerous patients with ulcer of the stomach seldom vomit more than a small portion of their food; whilst Dr. Davis had pointed out that when cancerous disease of the stomach had existed for several months, the patient will often go from four days to ten without a passage from the bowels, and still the abdomen will be lank and empty.

The President thought that, if the ulcer had arisen from the abuse of ardent spirits, similar cases would be often met with; whilst the specimen exhibited was very rare and interesting.

The Secretary read notes of two cases of lupus erythematosus.

Paper:¹ DR. H. S. PURDON made the following observations on this comparatively rare disease:—I have had two cases of lupus erythematosus recently under treatment, and rather than describe them separately I will take this opportunity of saying a few words on the disease. Both patients were females—one, Mrs. T., aged fifty. In her case the disease occurred on the chin, commencing ten years ago as a small red spot, which became covered by a tenacious scab, nearly impossible to remove; it slowly spread, and when seen by me was about the size of a two shilling piece, mottled at one side—this white appearance being due to the growth of new white fibrous tissue. Her family history was bad, phthisis having carried off several of her relations. The treatment adopted was frictions with juniper tar soap, painting the part afterwards with a calamine lotion. Subsequently I prescribed a weak iodide of sulphur ointment, and tonics internally. The disease, after five months' treatment, is now cured. My other case, which I attended at the same time, occurred in the person of Mary P., aged twenty, a mill worker. Both cheeks were attacked, as was also a part of the left ear. The skin was red; orifice of gland ducts plainly visible, and filled with "horny exuvizæ," bearing out the view of Hebra that the disease is, in the first instance, an affection of the sebaceous glands, or a seborrhæa congestiva, as he calls it. In this case I ordered a preparation containing oil of cade, and a mixture of iron, wine, and Fowler's solution. The disease is slowly improving. When the disease occurs near the scalp permanent baldness is produced. In both these cases the disease will terminate in a white depressed cicatrix. Biett called this disease erythema centrifugum; but, as Erasmus Wilson observes, "at a first glance the patch appears trifling; its stationary

¹ [Dublin Journal of Medical Science, 1874, v57, p390.]

¹ [Dublin Journal of Medical Science, 1874, v57, p388.]

habit and resistance of treatment excite suspicion that it is something more than common erythema, and its disposition to occasion atrophy of the skin proves it to be more serious in its nature, and when it fortunately disappears spontaneously, the white cicatrix indicating the removal of the papillary layer of the derma, or, on the scalp, the destruction of the hair follicles, declares its relation to lupus." I recall to mind the case of a young lady who was under my care for this disease some four years ago, and it made sad havoc of her face; both sides were involved, and the hair all gone at both temporal regions. The disease under notice often attacks the fingers and toes, and is then confounded with chilblains; it is sometimes associated with lupus non-exedens. In lupus erythematosus, as well as in lupus non-exedens, the capillaries going to a lupus papule or patch are twisted round the clubby kind of cells. In the first mentioned variety it is the true skin that is chiefly involved; whilst in the other, or non-exedens, it is the connective tissue of the skin that is affected. As pointed out by Volkman in lupus erythematosus, the skin is often at first covered by a leafy crust, generally symmetrical. Where the nose and both cheeks are affected it has been compared to a butterfly with wing expanded. This crust adheres tenaciously to the reddened skin, and has often an unctuous feel. If this crust is removed the skin underneath is found red and apparently purely papillary, the latter appearance, by aid of a lens, is seen to be due to a number of minute orifices closely set together, which are the openings of sebaceous glands much dilated, and the crust is caused by their secretion. Volkman holds that in addition to the seborrhœa there is infiltration of lymphoid elements. I may say that in my recent case I was able to point out all these characters to the gentlemen attending my clinique at the skin hospital. The treatment has already been touched on; however, it has been suggested to remove the crusts by lint soaked in oil, and then washing the diseased part with a good lather of soft soap. If this fails strong liquor ammoniæ or liquor potassæ is applied, or iodine, iodide of potassium and glycerine pencilled on the part; others prefer Rochard's ointment, composed of calomel, iodine, and conium ointment. Carbolic acid has also been tried. As in the other varieties of lupus, internal remedies are useless, it is to local means we are to trust.

Dr. M'Crea considered that constitutional treatment was most important in all forms of lupus, and held that the disease was generally connected with scrofula.

DR. WALTON BROWNE mentioned a curious skin affection occurring on the fingers and toes, chiefly the latter, in the boys who are sent on board the "Gibraltar" training ship in Belfast Lough. The skin becomes red, vesication then occurs, and an indolent ulcer ensues. He thought the disease allied to erythema gangrenosum; that it was not chilblains was proved by the fact that it occurred during summer as well as winter. He had found resin ointment and good diet the best plan of

treatment. When the toes were attacked the ankles usually became œdematous.

DR. H. S. PURDON replied that he thought the local treatment of lupus, especially by what is called "heroic" means, the best plan, and had no faith in a "soothing" plan of treatment, except at first, when symptoms of irritation were present. He noticed that erysipelas had cured lupus vulgaris of the face. Dr. Purdon referred to Dr. Theodore Veiel's treatment of lupus. The best results being obtained by chloride of zinc in solution in alcohol and applied to the affected parts, which had in the first instance been blistered. This treatment is very painful, and not likely to be submitted to by Irish patients.

John Moore, Chairman
Ulster Medical Society. The Sixth Meeting of the Society was held on Thursday evening January 22nd 1874.

The President in the chair. Members present Professor Dill, Drs. Aickin, Stewart, Fagan, Walton Browne, Stewart, Whitla, David Johnson and H. S. Purdon.

Dr. David Johnson proposed and Dr. Walton Browne seconded a motion "That Dr. McMurtry be re-elected a member of the Society."

Dr. Whitla exhibited a horseshoe kidney and Dr. David Johnson gave notes of a case of postpartum hæmorrhage.

Paper:¹ DR. WHITLA, house surgeon, Belfast General Hospital, read the following notes:—

Maria C., aged seventeen, unmarried, certified to be labouring under gastric fever, was admitted into hospital on 3rd December, under care of Dr. H. S. Purdon. She had been in good health until five days previously; had menstruated only once, and that was five months ago.

On her admission she was very weak and restless; face pallid; eyes staring, and respiration quick and panting; skin cool and dry; temperature 98.1°; pulse rapid and weak; tongue moist and coated, with red papillæ projecting; but the most prominent symptom was persistent vomiting. In this state she remained for seven days, in which she was treated for an attack of gastritis; sinapisms over the stomach. Liquor bismuthi produced little change. Afterwards oxalate of cerium was given with benefit.

On the 12th December some œdema about the ankles appeared. Her urine was examined and abundance of albumen found in it. There was no doubt now about the nature of the disease. The œdema spread rapidly. She got gradually worse. On the 15th January she lost power of one upper extremity. On the following day the corresponding lower limb was paralysed, and on the evening of the same day she died, being comatose for some few hours. The only food that

¹ [Dublin Journal of Medical Science, 1874, v57, p391.]

remained on the stomach was buttermilk.

DR. FAGAN, from the appearance presented, considered that the cortical substance of the kidney was changed. He did not think a horse-shoe kidney a rarity, nor would its shape interfere with the due discharge of its functions.

Dr. Aicken thought the specimen was a curiosity. It had two pelves and connected ureters.

Professor Dill stated that he had often met with great irritability of the stomach in cases of Bright's disease, he had found the new preparation called "Koumis" succeed in allaying the irritability, and he supposed that the buttermilk that the patient took acted in a similar manner.

DR. H. S. PURDON said that the patient from whom the kidney exhibited was taken had been under his care in the hospital. The dropsy was not urgent; in fact, the vomiting was the most pressing symptom, and he had to treat symptoms. The oxalate of cerium succeeded in checking it. The only food she lived on for many days was buttermilk. He had tried the koumis in two cases of diabetes, but not in Bright's disease. He thought that the great irritability of the stomach and constant vomiting in this case were due to retained urea, which, as pointed out by Todd, often gave rise to retching and irritability of the mucous membrane of the stomach. He noticed that persons who had undergone the "Banting" system for the cure of corpulency were very liable to Bright's disease, from absorption of the fat that surrounds the kidneys, and he believed that the case under discussion was one of tubal or epithelial nephritis, affecting mainly the epithelium of the tubes and ultimately producing the large smooth white kidney. In addition, Dr. Purdon said that there existed slight hypertrophy of the left ventricle; and in these cases it had been found by Dr. Galabin that the arterioles corresponded in all respects to those of the granular kidney; and the state of the minute capillaries, often apparently fatty, with more or less hypertrophy of the muscular coats of the arteries, is due to increased arterial pressure, as proved by the sphygmograph. The epistaxis and hæmorrhage in the retina, or even cerebral hæmorrhage, are due to the degeneration in the walls of small vessels.

DR. WHITLA, in reply, said that the diarrhœa which had existed for a few days in the case might be explained on Johnston's theory, viz., that the retained urea was excreted by the intestines as carbonate of ammonia, and that the buttermilk would act as a neutralizing agent and sedative, which might account for the patient's craving for it.

Paper:¹—DR. DAVID JOHNSTON brought under the notice of the Society, the case of a patient aged 21, whom he had attended in her first confinement. The labour was natural; but pains feeble; child still-born. He

left her doing well at 2 o'clock p.m.; sent for at 6 o'clock p.m., and then found more or less oozing; emptied the uterus, and, when the loss had stopped, left. Again visited the patient at 10 o'clock p.m., being sent for; there was profuse hæmorrhage; pulse feeble, indeed nearly imperceptible; emptied the uterus of several clots, and, as the case was urgent, he injected 2 ounces of the perchloride of iron in 20 ounces of water, which, for the time, arrested the hæmorrhage. In about half an hour it recommenced; he then repeated the injection, and obtained the assistance of the President. The patient at this time was in great danger; tossing her arms about, sighing and restless. He injected the iron solution for the third time, 2 ounces to about 8 ounces of water. He thought that his first injection had produced little effect, as he had to do everything himself; but the others succeeded in stopping the hæmorrhage. Some surgeons look on the injection of iron as a dangerous remedy, but, in his case, the patient made a good recovery, there was no tenderness over the uterus at all. Ergot failed completely in this case.

Dr. AICKEN said that if the placenta be soft, in the expulsion from the uterus, it sometimes tears and leaves part behind, and from this internal portion and its attachments oozing may take place. In a case of his, he had tried a sponge wrung out of vinegar and rolled round the uterus, which immediately brought on the uterine contractions.

Dr. Fagan noticed the beneficial effects of transfusion, in cases of severe post-partum hæmorrhage.

PROFESSOR DILL considered that the case under the notice of the Society was very interesting, and from what he could gather from the remarks of Dr. Johnston, the iron injection had suited best. He did not think that as yet we could pronounce a verdict, so to speak, on the value of the perchloride of iron. In this case, the hæmorrhage arose from want of contractility of the uterus, as was proved by the hæmorrhage coming slowly and gradually. In such a case the injection of iron is useful. If such a case presented itself in his practice he would, in the first instance, attack it by the application of cold. He seldom had seen a case of post-partum hæmorrhage that did not yield, if treated promptly, to the sudden application of cold, especially iced water, if it could be obtained, if not, then a handful of salt might be added to the water. In some cases the hæmorrhage could be anticipated by the character of the labour pains. If they are feeble and irregular, hæmorrhage may be expected. Ergot of rye, he thought, was useful only in some stages of labour, and ought to be given when the pains were feeble, giving rise to irregular contractions of the uterus. The drug was especially serviceable during the last three or four pains, just before expulsion. At this stage it certainly occasioned good contraction of the uterus, and he had little faith in ergot after the expulsion of the child. The circulation when quickened in those of a full habit of body—as shown by a quick pulse,

¹ [Dublin Journal of Medical Science, 1874, v57, p392.]

often gave rise to hæmorrhage. In such cases previously to labour much could be done in the way of treatment, by quietness, by keeping the patient cool, and administering those remedies which quiet the heart's action, as digitalis. Want of coagulability of the blood was another cause of hæmorrhage. In such cases gallic acid is useful. The Professor had formerly held the idea that when a patient died from post-partum hæmorrhage, it was generally the medical attendant's fault. Recently he had seen, chiefly in consultation, some three or four cases which were fatal, and he had changed his opinion, and chiefly for the reason that in all these patients there seemed to be a general varicose condition of the veins in the limbs and elsewhere, showing disease of the venous system. These cases were very dangerous, and he held that there was probably the same state of the uterine veins. In conclusion, he thought it might be worth while trying the plan of applying a tourniquet to the extremities, to stir up the blood in cases of post-partum hæmorrhage.

The PRESIDENT stated that during the 26 years he had practised his profession, he had been peculiarly exempt from cases of post-partum hæmorrhage, and had only one death from this cause. The case under notice was, what might be called, an extreme case, at the verge of death, and the treatment adopted was not only proper, but necessary. He had, in similar cases, compressed the aorta; but he believed that the injection of the solution of iron was more rapid and suitable. On examining the parts afterwards, the vagina would hardly admit the finger, showing the contracting power of the iron.

John Moore

Ulster Medical Society. The Seventh Meeting was held on January 29th.

The President in the chair. Members present Drs. Walton Browne, Charles, Murney, Cuming, Whitla, James Moore, Garde and H. S. Purdon.

A subcommittee consisting of the President, Drs. Smith, Murney, Whitla and H. S. Purdon were appointed to examine into the state of the library.

Dr. McMurtry was voted for and duly elected a member of the Society.

Dr. Murney exhibited a specimen of diseased knee joint and read notes of an interesting case of post-mortem.

Paper:¹—DR. MURNEY exhibited a diseased knee-joint which required amputation at the lower third of the thigh, and gave the following history of the case:—The patient was a female, aged 24. About four years previously she had, as he believed from the description given, acute synovitis of the knee, which passed into the chronic stage, accompanied by occa-

sional exacerbations. The swelling of the joint never completely diminished. Some four months since, ulceration of the cartilages commenced, and she then sought admission into the Belfast General Hospital. Last Saturday, January 24th, he amputated the thigh. She slept soundly the night after the operation; previously she had required large doses of anodynes; she is now progressing favourably. Upon examination the cartilages show extensive ulceration, in some places the cartilage of incrustation is completely gone. Moreover, the head of the tibia is eroded and greatly diseased. Some surgeons might think that excision should have been employed, but his experience, derived from the General Hospital, was opposed to that operation.

The first case of excision of the knee-joint performed in the General Hospital was in 1850, by the late Dr. H. Stewart, and since then the results of the operation had been very unsatisfactory. Dr. Murney thought that excision of the elbow-joint gave much better results, and held that excision of the knee-joint was not a suitable operation, when the patient belonged to the working classes, whilst amongst those in a better position in society the results were more hopeful. In the former he preferred amputation; with regard to the production of a "stiff joint," he thought that it might be tried in certain cases, and was better than excision.

Dr. James Moore stated that he was not in favour of the operation of excision.

Dr. H. S. Purdon proposed and Dr. Murney seconded the following "That Andrew Spence L.R.C.P.&S. Edin., Henry Murray M.D. L.A.H., Samuel McKee M.D. M.Ch., William Rankin L.R.P.&S. Glasgow, be elected members of the Ulster Medical Society."

Case published under the title "Transactions of the Ulster Medical Society" in the Dublin Journal of Medical Science, 1874, v57, p394.

January 1874

Delirium Tremens.—Dr. H. S. PURDON read the following notes of a case:—

Ordinary cases of delirium tremens are generally well within 48 hours, by inducing sleep. Occasionally, however, more obstinate cases arise. The following are the notes of one that has recently been under treatment in the general hospital.

Francis P., aged 48; married; by employment a publican; a powerful and well-made man, was admitted into hospital on January 7th, 1874, labouring under delirium tremens. He had been a "heavy drinker," and drank more than usual a short time before his being taken to hospital. The assistance of the police had to be obtained by his friends, so as to bring him to us. After his admission, he was quiet, but became very violent when anyone entered the cell in which he was confined. He was prevailed on to take a chloral draught at night,

¹ [Dublin Journal of Medical Science, 1874, v57, p396.]

and slept 4½ hours. Next day he was very violent, dangerous, and delirious, had hallucinations of both sight and hearing, and was suspicious of everyone. The straight jacket had to be put on him; however, during the evening he became quieter, and the jacket was removed.

January 9th.—Again became very violent and delirious, so as to necessitate the use of the straight jacket. Tongue is now moist and creamy; skin perspiring (hitherto it was dry); pulse 80, and soft; bowels moved; urine normal. Has not slept, although on the 8th and 9th he had chloral in ʒi doses, which had little or no effect, indeed it seemed to make him worse, and to increase the heart's action.

10th.—Much the same. Was ordered a mixture of opium and tartar emetic, and a purge of jalap powder.

11th.—Somewhat better; complains of "noise in the ears," and wishes his "brain to be examined," will submit, and requests his head to be "cut open," inclined to pray on every opportunity.

12th.—From this date till 17th, much quieter; bowels regular; appetite good; tongue clean; pulse fair. Occasionally quite rational, but always in a melancholy state. Ordered ergot, bromide of potassium, bromide of ammonium, iodide of potassium, in a bitter infusion.

17th.—When seen this morning he was very low. Muscles somewhat rigid; pulse weak; body bathed in sweat; won't open his eyes; complains of people talking to him. Ordered an enema of 10 grains of quinine and starch, and blister to neck. From the first (with the exception of one day) till 16th inst., he had ʒiii of whiskey given in milk, eggs and beef-tea.

18th.—Better; the stimulant (brandy) he had yesterday, during the sweating stage, roused him up, and stopped the sweating. Ordered to-day, a purgative of jalap and calomel, and the cold water douche. This profuse sweating may be due to vaso-motor nerve paralysis, and, as remarked by Anstie, prolonged alcoholic poisoning induces degenerative changes, due to direct chemical influence of alcohol upon the nervous tissue, causing paralysis of the nerves that preside over nutrition.

19th.—At the suggestion of Dr. Wales, under whose care he had been on former occasions, he was ordered some claret daily.

Jan. 24th.—Patient sleeps well, eats well, and seems in good bodily health, but still complains of hallucinations of sight and hearing, which, however, he knows perfectly well are false.

As in all cases of delirium tremens, there was in this patient well marked tremor and quivering of the tongue. The obstinate nature of the attack might be due to perverted nutrition of the brain, from the circulation of impure blood. As pointed out by Tanner, there is, in severe cases, often an increase of urea, with diminution of phosphates in the urine. Dr. Laycock, who has investigated the disease under notice, thinks that sleepless-

ness is not so serious a matter as is supposed in delirium tremens.

No doubt there are two forms of this disease, viz.:—The acute and the chronic, the latter usually attended by mental and bodily depression. It is a curious and well known fact, that nearly all delirium tremens patients imagine that they see the devil, at some part of their illness. My patient thought that several devils surrounded him, urging him by voice to attack his attendants.

Dr. Blandford writing on auditory hallucinations (Journal of Medical Science, January, 1874) such as existed in the case I am describing, as well as hallucinations of sight, states that "the patients tormented by voices were more than commonly stout, and that hallucinations of sight belong to the acute rather than to the chronic stages of insanity."

He defines the distinction between hallucinations and illusions to be "that an illusion is said to be a false interpretation of a real sound, while an hallucination is a false perception of a fancied voice or sound when there is no sound at all in reality." Dr. Barclay, on this subject, holds that "in the strict application of terms, the word hallucination implies that no object is present to stimulate that organ to which the idea formed in the mind is referred; while in illusions, existing objects which, in the first instance, produce the stimulus are clothed by the mind in characters more or less foreign to their true nature, and so blended with the sensation originally produced, as to give rise to the belief that the resulting idea is wholly derived from the external impression."

With regard to the treatment of delirium tremens, as debility is generally exhibited, nourishment, such as plenty of milk, eggs, and, in some cases, a moderate allowance of stimulants is, I think, necessary. I have remarked that when the patient is pale, thin, and not a confirmed tippler, and has not the greasy unctuous skin "reeking with volatile fatty acids," so characteristic of the drunkard, that Graves' plan of treatment by tartar emetic and opium, succeeds very well; however, opium sometimes stimulates, even when guarded, so to speak, with antimony. A good purgative is a capital preparation for this, or indeed any plan of treatment. Chloral is useful, and is now the popular remedy for delirium tremens, but, as remarked in this case, does not always agree, and often seems to stimulate the heart and brain. Red pepper in twenty grain doses has not succeeded in my hands, nor has bromide of potassium. I have had no experience of the tincture of digitalis in ½ ounce doses, as recommended by Jones of Jersey, nor of the hypodermic injection of caffeine, except in neuralgia. For the tremor and "unsteadiness" that remain after an attack of delirium tremens, the oxide of zinc in two grain doses thrice daily has done good, or, if the appetite is bad, quinine given with the ammoniated tincture of valerian, may be ordered. I believe that when renal con-

gestion occurs the disease is very often fatal, ending in convulsions, coma, and death. In conclusion, my chief object in bringing this case under the notice of the society, is not that I have anything new to offer in the way of pathology or of treatment, but to elicit the views of the members as regards the treatment, etc., of, I am sorry to say, a very common disease.

Ulster Medical Society. Eighth Meeting of the Society was held on February 11th.

The President in the chair. Members present Drs. Dill, Stewart, Fagan, McMurtry, Charles, Gribbin, Spedding, Scott and Hon. Secretary.

Before the business of the meeting commenced the President brought under the notice of the Society the death of an old and valued member Dr. William McGee J.P. and it was proposed by Dr. Stewart and seconded by Dr. Dill that the Secretary be directed to write a letter of condolence to the deceased gentleman's family.

The following were then balloted for and duly elected members of the Society viz. Andrew Spence L.R.C.P. Edin., Henry Murray M.D. L.A.H., Samuel McKee M.D., William Rankin L.R.P.&S. Glas.

Dr. Fagan exhibited a specimen of cancer removed from breast and Dr. Dill showed a tumour expelled from uterus.

Paper:¹ DR. FAGAN exhibited a specimen of cancer which he had removed from the breast of a female, aged thirty-two, unmarried. About three months ago the patient first noticed the tumour, and felt pain in the affected part. She exhibited no cancerous diathesis. Some surgeons do not approve of the removal of scirrhus, but Dr. Fagan held that in this case operative interference was not only suitable but necessary, the case being most favourable in all respects for excision. There was only one gland enlarged in the axilla, and that from irritation.

SURGEON GRIBBIN considered it judicious to remove not only the diseased mass, but also any enlarged glands that existed. He had under observation a patient who had been operated on in the General Hospital twelve years ago, and the disease had not returned.

Dr. Spedding believed that the younger the patient, the more liable she was to an early return of the disease.

DR. M'MURTRY doubted the necessity for operative interference in such cases, and did not see clearly the reason why some surgeons thought it so desirable to operate, as he held that the local cancerous deposit resulted from constitutional conditions which could never, he thought, be removed. After removal of the cancerous mass, other local deposits were very apt to occur.

DR. CHARLES said that if the glands in the axilla were

enlarged, they should be removed, and this enlargement was generally due to cancerous material being carried to them. Many eminent authorities looked on cancer as a local disease, and held that prompt removal was necessary. It is impossible to remove all the enlarged glands, as the lymphatics pass from the axilla to the thorax behind the sternum.

PROFESSOR DILL believed cancer to be a blood disease, which could not be removed. From his own experience he held it to be bad practice to remove a scirrhus breast, as he had generally seen the disease return not only rapidly, but in a more malignant form, and then the disease had no material, so to speak, on which to expend itself. He had seen scirrhus of the breast removed from a female, aged twenty-six, and return inside one year; it was again removed, and she died from the same affection in a year and a half. Two of his own patients who had scirrhus of the breast, which had not been operated on, lived upwards of ten years.

Dr. Scott asked if any of the members had any experience of condurango given in this disease.

The President remarked that, from his experience, he undertook no surgical operation with more hesitation than that of the removal of a cancerous breast, owing to the great liability of the disease to return, and he had never met with a case where it did not show itself again.

Paper:¹ PROFESSOR DILL exhibited a tumour expelled from the uterus. He said that the patient was aged fifty-six; her catamenia ceased at fifty. Last year she thought that her menstrual periods had recommenced, as the loss occurred monthly, accompanied with pain. The uterus descended so low that it could be seen and felt, and the patient's daughter had often returned it with her finger. He was called in consultation.

The patient had lost a good deal of blood, and the hæmorrhage still continued. The tumour was at the vulva, and its size, as was apparent to the members, was that of a goose egg, and of the shape of the uterine cavity. Tumours of this kind were usually fatal to the patient, and connected with the uterus. In structure it was musculo-fibrous. The pedicle was only the size of a large blood-vessel.

DR. CHARLES thought that the tumour had originally occurred in the uterine walls, which had given way when the growth had fallen into the cavity, and got moulded to its shape. This would also account for the absence of a pedicle.

John Murray

Ulster Medical Society. Ninth Meeting during present session was held on February 19th 1874.

The President in the chair. Members present Drs. Barnett, Dill, Fagan, Murray, Rankin, J. W. Browne, Sped-

¹ [Dublin Journal of Medical Science, 1874, v58, p73.]

¹ [Dublin Journal of Medical Science, 1874, v58, p74.]

ding, Moore, Stewart, Wales, Johnston and H. S. Purdon.

The minutes of previous meeting having been read and confirmed, a discussion on the aspirator then took place in which the President, Drs. Dill, Fagan, Browne, Purdon, Moore and Spedding joined.

Paper¹—DR. H. S. PURDON said that he had recently read Dr. Dieulafoy's book on the aspiration of fluids, and was much struck with several of the statements contained therein. For instance, that if a congested lung be punctured, the needle may be left in situ, and a few drachms of blood abstracted, thus producing a true blood-letting of the affected organ. Dr. Purdon's experience of the aspirator was very limited, as he had used the instrument only in some eight or nine cases of pleuritic effusion. The patients were all males, and were under treatment in the Belfast General Hospital. In about half the number the effusion was purulent, and in such cases he did not think the aspirator so useful. He punctured near the inferior angle of the scapula. Now, when the trocar and cannula were formerly used, we were directed to select a high site—for this reason, that when nature produced a fistulous opening, such a situation was chosen. Two of his cases were complicated with tubercle, in which, of course, the treatment by aspiration was only palliative. In another case the disease was hydro-pneumo-thorax, and from this patient four pints of clear fluid were drawn off. The amphoric echo was present before tapping, after which operation metallic tinkling occurred. However, as the fluid again accumulated, this disappeared. In this same case no fluid was obtained on the first puncture, which was at the back, and where one would expect the fluid to gravitate to, but it was obtained anteriorly. It is not always possible to draw off all the fluid, as difficulty of breathing, pain in the chest, and troublesome cough occur. In some, bloody expectoration takes place, which is said to indicate puncture of the lung. In patients where the effusion is of small quantity, the fluid may occupy a conical portion of the pleural cavity—near, say, to the axilla, and when both resonance and respiration are wanting. Dr. Purdon next referred to "Damoisseau's curve," which, it is said, tends towards estimating the amount of fluid effused—namely, when the fluid is being absorbed, and reaches a level of seven centimetres above the nipple, the line of dulness is horizontal, and when the effusion is less, the line of dulness is curved, the highest point being at the side, from which it gradually falls as it approaches the median line towards the spine.

PROFESSOR DILL stated that he was satisfied that the aspirator was the most important instrument introduced of late years. He had formed a high estimate of the aspirator, and within the last three months he was sent for in consultation to see a lady residing in the

country, who was aged about fifty, suffering from strangulated umbilical hernia. Every effort was made to reduce the rupture, but without success. He thought it a fair case for using the aspirator, which he had sent him from town. The hernia was fully the size of an infant's head. The intestine was filled with air. After using the fine needle and aspirator, immediate relief was afforded, and the tumour collapsed. The patient ever since had done well.

Dr. Fagan had used the aspirator in a great number of cases, but he thought that, like all new instruments, its powers were overrated.

However, he had found it very useful in cases of abscess, when the collection of pus was large, and when it was desirable to draw off the fluid gradually. A child, aged six, was under his care in the Children's Hospital, with hip-joint disease, which had caused a large abscess in front of the thigh, and to open which in the usual way would have been nearly impossible. He used the aspirator daily, and thus removed the pus. In some cases the abscess burst afterwards. He had used the aspirator in a case of effusion into the knee-joint with good results, and the fluid could not be removed by the ordinary methods of treatment. In this case he drew off an ounce of serum, with immediate relief, and the patient recovered well without any one bad symptom.

DR. JAMES MOORE had used the aspirator for abscess in the outer parts of the thigh in a woman, an inmate of the Hospital for the Insane. As the patient was troublesome, he did not like to open it in the usual manner. He drew off 16 ounces of thin pus. He looked on the aspirator as a most valuable instrument.

The PRESIDENT thought that, in introducing the needle, in some cases a little incision through the skin might be useful, as it was not always safe to plunge into an abscess, especially with a large needle. He had tapped a knee-joint with the aspirator. In hernia distended by flatus the small puncture was to be preferred.

Dr. Barnett read a paper on fracture of inferior maxilla and exhibited casts of bone etc.

Paper:¹ IN 1836, a man named Macdonald, a coachman in the service of a gentleman residing a few miles from Belfast, returning one evening to his master, was waylaid and knocked down; when on the earth his assailant gave him a kick with a heavy shoe, which fractured the lower maxillary bone at the symphysis. The man was admitted into hospital, but, at the end of three months' treatment, union of the fractured surfaces had not taken place, and he was discharged. He was now placed under my father's care.² There was a space of half an inch between the extremities of the fractured bone, one extremity being drawn in towards the base of the tongue. The four incisor teeth and abve-

¹ [Dublin Journal of Medical Science, 1874, v58, p74.]

¹ [Dublin Journal of Medical Science, 1874, v57, p397.]

² [Also Richard Barnett, described as a dentist in Professor Richard Clarke's book A Directory of Ulster Doctors, Belfast 2013, UHF.]

oli containing them having exfoliated, the most anterior teeth that presented themselves were the right and left canine teeth. A ligature of silk was tied firmly around the canine tooth of that portion of the bone which was drawn inwards toward the base of the tongue by the action of its attached muscles. One assistant had charge of this—another, by means of a small instrument, like a fork, fitted to the neck of the other canine tooth, pressed that portion of the bone backwards, and so reduced the fracture as to leave the mouth free from anything that would interfere with the subsequent steps of the operation.

Bees' wax was softened and placed in a frame suited for taking impressions from the lower maxilla. This was carefully introduced into the mouth, and an impression taken of the space in the front where the incisor tooth had been, and of all the remaining teeth on both sides.

From the cast now taken a frame of silver was made, which fitted all the teeth of the lower maxilla, and dipping down from the apices of the canine teeth on each side to fit the space between these teeth. The silver capping-frame was now introduced into the mouth, and found to fit the crowns and exposed surfaces of all the teeth, and the space in front; but the man had no command over his jaws, and there was a strong involuntary lateral movement which was to be overcome, or the steps hitherto taken would have been useless.

A strong silver bar was now soldered on the outside of the frame, and in a vertical position, so that when the month was closed, this bar passed between the buccal surface of the superior molar teeth and the cheek of that side of the frame to which it was soldered. This effectually prevented lateral movement in the opposite direction, which may be readily understood. A second bar was now attached to the opposite side of the frame, having the same relation to the superior molar teeth on that side. There could now be no lateral movement to either right or left side.

It now remained to make arrangements for feeding him, and that was managed in the following way. A silver bar was soldered to that part of the frame which covered the apices of the canine teeth, thus leaving a considerable space from the inferior margin of that bar to the frame covering the surface of the gum, and through this space he was fed. This bar also strengthened the frame, which at this part most required it, as it was more liable to injury at the central part.

This apparatus—consisting now of a frame, fitting all the lower teeth and gums, having two side bars in a vertical position, and one bar in the centre, passing from the apex of one canine tooth to the other, the space for feeding the patient being underneath this bar—was placed in situ, and the bandages passed round the vertex of the cranium in the usual manner. The patient, being directed not to interfere with the mecha-

nism or disturb the bandages, went to the country.

At the expiration of six weeks he returned, and the bandages being removed and the instrument taken out of his mouth, it was found that he could open and shut his mouth at pleasure, the teeth on the right side and left being on the proper level. However, as yet the union was principally cartilaginous, and would yield in a short time if left without support. The bones at seat of fracture were now rubbed, the one against the other, to cause irritation and excite more rapid ossification; and the frame being thoroughly cleansed—an operation it required very much—was replaced in the mouth, and the bandages applied as before.

He returned in three weeks, and it was found that he had the perfect use of the lower maxilla. He was recommended to keep the frame in his mouth for another fortnight, and then to return it; and as he was going to seek a new service in a distant locality, he was requested to call on a medical gentleman who resided in that neighbourhood, and who was much interested in his case, but he neither returned the frame nor revisited any of those gentlemen who had exhibited so much interest in his case.

Oblique Fracture of Lower Maxillary Bone.—On Dec. 24, 1872, I was asked by Dr. James Moore to see a boy, Christopher White, aged fourteen, then in the General Hospital.

A fortnight before, the lad had fallen out of one of the port-holes of the "Gibraltar" training ship, a depth of 17 feet, into a boat alongside, and Dr. Moore being on board the ship at the time, had him removed same day to hospital.

The lower maxillary was fractured obliquely, internally from a point beneath the right lateral incisor, running outwards toward the left canine tooth, the left central and lateral incisor teeth and their alveoli being also carried away at the time of the injury, leaving an ugly fissure.

An external wound under the symphysis, communicating with the cavity of the mouth, was almost healed when I saw him. The smaller portion of the bone was drawn in and downwards by the depressor muscles of that side, and there was a considerable amount of motion between the affected parts.

In order to restrain the voluntary and involuntary motion of the parts, and, at the same time, give room for the introduction of food, I made a vulcanite splint. I passed a waxed silk ligature between the bicuspid teeth on the left side; and while an assistant, by means of this ligature, reduced the fracture, and, at same time, retained the base of the bone in position, I introduced a metal tray of suitable wire, filled with soft wax, into the mouth, and thus obtained an accurate impression of all the teeth and contiguous gums, including the seat of fissure, having also taken an impression in wax of the teeth of the superior maxilla. From these impressions, plaster of Paris models were made—those marked No. 1

now on the table.

A vulcanite splint was now made to fit accurately all the teeth of the lower maxillary—to cap them, and to descend over the gums and alveoli, both internally and externally. The superior surface of this splint was carved out, so as to fit the grinding surfaces of the superior molars when the jaws were closed. On the left side a block of vulcanite was carried in a vertical direction, so as to fit the outside of the left upper molars when the mouth was closed, the object of this being to prevent all lateral motion.

On the 27th December this apparatus was introduced into his mouth. A piece of gutta-percha, previously softened in warm water, so as to take the mould of the external soft parts, was placed outside, under the base of the bone. This was semi-lunar in shape, and gave great support, some cotton wool being placed between the skin and the surface of the gutta-percha. Bandages were carried over the crown of the head, and around the neck, so as to steady all.

The following day I filled the upper surface of the splint at one part, so as to let the incisor and canine teeth on the right side through its surface. This made it more comfortable. The patient fed himself on soups and other fluid food, through the hole that can be seen by examining the models on the table. This space corresponds with the loss of teeth at the time of injury.

Two or three times a week the splint was removed from his mouth, cleansed with a tooth-brush, water, and soap, a mouth-wash, containing tincture of myrrh, being used at the same time.

Feb. 12, 1874.—The lad returned to his ship, able to do without the splint, and to give a very good account of a beefsteak; and the parts remain in a satisfactory condition at present date, fourteen months after fracture.

John Moore

Ulster Medical Society. The Tenth Meeting during present session was held on February 26th 1874.

The President in the chair. Members present Drs. Stewart, Spedding, Charles, Whitla, Purdon, Wales, J. Browne and Rankin.

Dr. Whitla exhibited a forearm removed that day.

Dr. Charles showed several interesting specimens of osteo-arthritis of shoulder and hip joints.

PAPER:¹ DR. CHARLES exhibited some interesting recent specimens of this disease. He thought that the name of chronic rheumatic arthritis was bad, as the affection was never attended by any of the complications of rheumatism, such as heart complications, nor was the disease gouty. In some of the specimens of the shoulder-joint which he showed to the members, the head of the humerus was enlarged, and had a porcel-

laneous deposit. In others the biceps tendon was removed or flattened, whilst in one case there existed also fatty degeneration of the muscles of the thumb and fingers. The cause of dislocation at the shoulder was the removal of the supra-spinatus muscle by absorption. The capsule of the joint then became softened, as also the infra-spinatus, and the remaining muscles drew the bone upwards. The name of osteoarthritis, Dr. Charles thought, did not bind one to look on the disease as rheumatic or gouty.

Dr. Whitla said that the fatty degeneration of the muscles of the hand observed in one of the specimens might be accounted, for by the fact that motion was greatly impaired, and thus the muscles degenerated and atrophied. In this case there was also deposit about the finger-joints.

Dr. Spedding read notes of cases of cystitis.

PAPER:¹ MR. President and Gentlemen,—I do not pretend to bring anything new or original before you to-night in the treatment of cystitis, but merely to record the result of four cases, all treated upon the same plan, by a remedy which was twenty-nine years ago extolled in the writings of Dr. Robert M'Donnell, of Montreal, in such a manner as to warrant one in giving it a fair trial.

It consists of injecting the bladder with a weak solution of nitrate of silver at short and repeated intervals.

This practice, though possibly known to all of you, is, I venture to state, very rarely adopted, inasmuch as I do not remember any of my professional brethren so treating this disease during my studentship, or since I entered into practice.

The disease is so common that all men who have an extensive field for clinical observation must have noticed how little good effect is produced by the use of various internal remedies which from time to time have been recommended for the cure of sub-acute and chronic inflammation of the bladder. The effect of the use of nitrate of silver injected into the diseased bladder has been so successful in my hands that I think it may be interesting and instructive to read the notes of each case before this Society.

CASE I.—John M'Alister, engine driver, married, aged thirty-two, consulted me on the 20th March, 1873. He stated that about eighteen months previously he commenced to suffer from severe pain in making his water, and being in Edinburgh at the time, became an indoor patient of the Royal Infirmary of that city for a period of six weeks. Here he was treated by internal remedies, and being unimproved, left for Belfast. Shortly after his arrival he consulted me, complaining of frequent desire to micturate, and great pain in doing so, the stream often stopping, and some blood coming away from the urethra. The symptoms of stone were so strongly marked that I passed the sound three times, with a neg-

¹ [Dublin Journal of Medical Science, 1874, v58, p76.]

¹ [Dublin Journal of Medical Science, 1874, v58, p69.]

ative result. Upon his second visit he brought me a specimen of his urine, on allowing which to settle in a test tube it took on a four-fold arrangement, the lowest fourth being blood, next pus, next tenacious mucus, the supernatant fluid being clear urine, having a strong alkaline reaction. I put him on a mixture of nitrohydrochloric acid, tincture of hyoscyamus, and infusion of buchu, an opiate, and a hot hip bath at bedtime. Continued this for three weeks with no benefit, the urine presenting exactly the same appearance, and being as alkaline, as before. I, then, determined to inject his bladder with a solution of nitrate of silver. I passed a No. 8 elastic catheter, drew off the decomposed urine, and applying a half-ounce glass syringe to its outer end, injected twelve drachms of the solution (which was gr. ii. of the nitrate to a fluid ounce of distilled water). It gave no pain, but felt, as he said, rather warm; he went home, had his usual opiate, ten grains of Dover's powder, and a hot hip bath, and next day reported that he had slept better than he had done for several weeks. He came back every fifth or sixth day, and had altogether nine such injections. Upon each visit he brought me a specimen of the morning urine. The blood disappeared altogether after the second injection, and the mucous and pustular discharge was greatly diminished. At the end of the third week of this treatment he had to rise only twice at night to urinate, whereas he was formerly up every hour. After the ninth week he stated that he felt quite well, and when I examined his urine under the microscope there was not a trace of blood, mucus, pus, or epithelium to be found. In May, 1873, he went to work. I cautioned him against the cold and the abuse of stimulants, to which he had been very partial, and lost sight of him until July, when I received a letter of thanks from him, stating that he was quite well. He was at this time an officer's servant in the South Down Militia, at Newtownards, where he was fortunate enough to escape the usual amount of marching drill, &c., in connexion with the annual training.

I was greatly disappointed when, early in September, 1873, he again applied to me, having, after an interval of three months' apparent cure, had a recurrence of all his symptoms in their most aggravated form. He gave himself up to dissipation after his discharge from the militia, drank whiskey for weeks without intermission, slept out in the cold, and got his bladder into such a state of acute inflammation that I could not again attempt the injection of caustic. Nothing could now check the progress of the disease. Blood, mucus, and pus came away from the urethra, even without making water; he emaciated rapidly, an uncontrollable diarrhœa set in, followed by uræmic symptoms, and he died, I believe, a victim to his own folly, early in December, 1873.

CASE II.—Ellen P., aged twenty, married, mill-worker, consulted me on the 3rd June, 1873. She stated that she had always enjoyed good health until a short time, some four or five weeks, after her marriage. She

had then to give up her work as a weaver, owing to a constant burning heat in her private parts, and a frequent desire to make water. Micturation pained her so much that she generally retained her urine for many hours from the dread of undergoing suffering. This state of things had continued for three months, and had been getting gradually worse, when she placed herself under my care. Upon examination per speculum I found the vagina highly inflamed, and the seat of a copious purulent discharge. On introducing the forefinger, and pressing upwards against the bladder, this patient screamed with pain. I drew off some urine for examination; it was normally acid, but upon allowing it to settle in a test tube it was more than one third pure pus. I diagnosed the case to be one of gonorrhœal cystitis, which the unfortunate bride had unconsciously contracted from her husband. I commenced treatment by injecting the bladder twice a week by an ordinary half-ounce glass syringe, with a solution of nitrate of silver, two grains to the ounce of warm distilled water. The first two injections gave a slight burning pain, followed by a desire to urinate, and were only retained a few minutes. The third injection, on the ninth day, gave no pain, and was retained altogether. This patient got ten such injections, with about four days' interval, and each specimen of urine which she brought to me contained less and less pus and mucus. She said that she could retain her water much longer, and was able, after the sixth injection, to sleep all night without requiring to urinate. In six weeks she was cured completely of her bladder derangement, but the vaginal discharge continued. This quickly yielded to the frequent use of the syphon syringe and astringent lotions. She has now continued quite well for six months, and has had no return of any bladder symptoms.

CASE III.—Christina D., a healthy married woman, aged thirty-two, and mother of six children, consulted me early in May, 1873. She stated that about twelve months previously she had over-heated herself while on a pleasure excursion to the sea-side, and that she got a chill by sitting on the grass and rocks. A few days afterwards from her account I gathered that she must have had acute cystitis, for which she received no treatment of any kind for three weeks, when she applied to a medical man, and took several bottles internally, without any benefit. She then tried another physician for a considerable time, and finally came to me, thinking herself incurable. To be brief, I found hers to be a bad case of chronic cystitis, with alkaline urine, containing large quantities of blood, pus, and tenacious mucus, together with phosphatic gravel. She was becoming emaciated from the pain and frequent calls to urinate during the night. As she had taken so much medicine internally without any benefit, I determined to treat her mainly depending upon the injection of nitrate of silver. I did so just as in the two former cases, and the result was most favourable. In the third week, after six injections,

the mucus and pus disappeared, and the blood was only visible when an occasional "attack of gravel" appeared. I then gave her a half-ounce glass syringe, and directed her to inject the bladder with a quarter of a pint of warm water every night, to which was added a tea-spoonful of laudanum. Being an intelligent woman, she did this properly, and after persevering in the treatment for four months, she became perfectly cured, and has remained well ever since.

CASE IV.—E. J., a gentleman, aged thirty, consulted me in June, 1873. He complained of scalding and pain, and frequent micturation, which he attributed to an imperfectly cured gonorrhœa which he had contracted several months previously. The discharge per urethram was little more than an ordinary gleet, but his urine showed chronic inflammation of the bladder, having a considerable deposit of pus and the characteristic tenacious mucus; the microscope revealed epithelium scales in great numbers; reaction slightly alkaline. I tried this patient with nitro-hydrochloric acid and infusion of buchu for one week, without any benefit, the condition of the urine being exactly the same as before its use.

I now injected his bladder in precisely the same way as case No. I.—viz., with two ounces of warm distilled water, containing four grains of nitrate of silver, and after the fifth injection had the gratification of finding him quite well, without the use of any internal remedy, save an opiate the night of each injection. It is now six months since the pus and mucus disappeared from his urine, and as I examined it very recently under the microscope, I am in a position to say that he is as well as before the attack commenced.

Remarks.—From the foregoing four cases I have come to the conclusion that we have in nitrate of silver a most potent remedy in the cure of cases of sub-acute and chronic cystitis. The injection causes little, if any, pain, and can be employed in cases of acid or alkaline urine. I am also of opinion that gonorrhœa, especially in women of the middle and lower classes, is a much more frequent cause of cystitis than has hitherto been thought.

DR. WALES believed that the nitrate of silver was serviceable in such cases as those described by Dr. Spedding, but he was at a loss to know how that remedy could be beneficial in the case described as being associated with phosphatic deposit in the urine. In cases of gonorrhœal cystitis the treatment recorded would be very useful.

DR. WALTON BROWNE remarked that Mr. Erichsen had mentioned the use of nitrate of silver in the treatment of cystitis. He had also tried it, and found it useful. Carbolic acid had, in some of his cases in dispensary practice, been serviceable.

DR. CHARLES thought that the best method of washing out the bladder was that described by Bryant. He had injected balsam of copaiva into the bladder in such

cases as those recorded.

DR. H. S. PURDON held that for chronic cystitis local treatment was the most important, and also that the urine should not be allowed to accumulate, as in cases where there was enlarged prostate or stricture. Acute cystitis was rare, as an idiopathic affection. He noticed a case, recorded by himself in the Dublin Medical Journal, where the disease was cured by the injection of normal urine.¹

The PRESIDENT believed that cases of cystitis were not very common. The nitrate of silver was an old remedy. The injection of balsam of copaiva, he thought, might give rise to formation of calculus, by some of the balsam remaining in the bladder.

R. Stewart, Chairman
5 March 1874

Ulster Medical Society. Eleventh Meeting of the Society was held on March 5th.

Dr. Stewart in the chair. Members present Drs. Whitla, Browne, Spedding and Purdon.

Dr. Whitla exhibited several interesting pathological specimens.

Paper:² Pericarditis.—DR. WHITLA exhibited a beautiful specimen of pericarditis, the whole surface of the heart as well as pericardium being covered by a thick deposit of lymph. There was also congestion of the lungs. He looked on this specimen, which had been taken from a patient under Professor Cuming's care, as an example of idiopathic pericarditis, as there was no rheumatic or syphilitic history or symptoms. The kidneys were also healthy. He intended to send the specimen to the Anatomical Museum of Queen's College, Belfast.

John Moore.

Ulster Medical Society. The Twelfth Meeting of the Society during present session was held on March 12th.

The President in the chair. Members present Drs. Wales, Charles, Purdon, McMurtry. Surgeons Whitla, Rankin and Spedding.

Dr. Whitla exhibited a diseased liver and ovary.

Paper:³ Abscess of Liver.—DR. WHITLA read the following notes:—Mary Bodel, aged thirty-five, married, mother of one child ten years old, was admitted to hospital on Monday, 2nd inst., suffering from typhoid fever. She was conscious and freely told her history. Had been in tolerably good health until seven days before admission, when her husband knocked her down and kicked her; she stayed out all night, and from that time had been complaining, but kept at her usual work

¹ [Dublin Journal of Medical Science, 1873, v56, p287.]

² [Dublin Journal of Medical Science, 1874, v58, p77.]

³ [Dublin Journal of Medical Science, 1874, v58, p77.]

for a week, when a very severe pain in the back compelled her to remain in bed; she got worse, and finally presented herself at the hospital, being attended by two physicians, who told her she had fever before seeking admission.

She had ceased to menstruate for seven months, having previously menstruated every fourteen days. Before admission some discharge came from the vagina, which, from the description given by the friends, seemed to be muco-pus. She had never suffered from jaundice, or complained of pain over the region of the liver. Never had any symptoms of ulcer of the stomach; no history of old diarrhœa. She had always resided in Ireland. Her friends stated that about one year previously her legs had swelled.

On examination, the skin was hot, tongue furred, head-ache, great pain in the back, sickness of stomach, no appetite, a good deal of thirst, cheeks circumscribed red, and face hectic in appearance, with great prostration, and temperature 103°. No eruption was visible. She had angular curvature of the spine in the upper lumbar region, and marks of old contusions. On percussing chest and abdomen negative results were found. No tenderness was felt anywhere except over region of uterus. Her most prominent symptom was an agonizing pain in the vagina, which was so distressing as to concentrate all her attention, and her friends believed she had contracted venereal disease from her husband, and attributed all her illness to this; there was no discharge.

March 3rd.—Morning temperature 102.2°; spent a bad night, seemed dull and stupid; the bowels having been up to this time in a fair condition, she was now attacked with diarrhœa, which lasted for two days, but was not very severe. Matter passed away involuntarily, she lay on her back with her knees drawn up, spoke little for hours, and would suddenly start exclaiming that the bed was on fire, and complaining of the pains in the vagina and back.

March 4th.—Morning temperature 101.9°. Had been very restless during the night; kept in the same position during the day; constantly kicking the bed clothes off; and, at 5 p.m., had a smart shivering fit, which lasted about ten minutes; did not speak. Her eyes were filled with mucous deposit; and now and then muttering delirium showed itself, and her pulse was too slow and full for fever. This last group of symptoms looked so like a cerebral case that the physician in charge pronounced it to be a brain affection. Her menstrual flow commenced; she had menstruated eight days before, being the first time for seven months.

March 5th.—Morning temperature 99.9°; much as usual all day; shivering repeated, but not so severe, lasting only a few minutes; no diarrhœa; no tenderness over the abdomen. Though speechless she was evidently conscious.

March 6th.—Morning temperature 100°, evening tem-

perature 102.4°. She remained as on the previous day, half comatose, till the morning of the 8th, when she died.

TEMPERATURES.

„ 7th,	—	—

Post-mortem.—No marks on the body; no evidence of suppuration anywhere, old or recent; in pretty fair condition. Head.—Membranes seemed somewhat congested; brain quite healthy. Fluid was found in both ventricles to the extent of one-half drachm; it was red and turbid. On microscopic examination it was found to contain many exudation-corpuscles and blood-cells. The folds of the choroid plexus seemed to be matted together in each cavity. Every part seemed otherwise healthy and free from even congestion. Chest.—Lungs perfectly healthy, structure entire, unusually pale. Heart very small in size but healthy; all the valves normal; vessels quite consistent with health; pleura and pericardium normal. Abdomen.—On opening this cavity everything seemed right, but on putting the fingers under the liver to tilt up its lower border, they went through into a great bag of pus, from which about three pints of thick creamy laudable pus escaped. The floor of the abscess was formed by a membrane composed of the thickened peritoneum and capsule; its roof by the burrowed out interior surface of the right lobe of the organ. When the purulent matter flowed away, the liver substance appeared like a coarse sponge riddled with cells. No membrane lined the greater abscess, nor was any trace of one found in the numerous recesses forming its roof.

On cutting into the organ little of its structure seemed left, it melted down at the gentlest touch, and pus oozed from every incision, except over a space about the size of the clenched fist of the left lobe, which was healthy and about twice as much tissue round this, only a little softened. On the upper surface of the organ the peritoneal covering was much thickened and blended with capsule and pus in quantity bagged between them and the proper liver substance. Gall-bladder was filled up by nine calculi, the largest of which was as big as a pigeon's egg; all weighed nearly half an ounce. Thick yellow pasty bile covered over these, and completely occupied the bladder. Ducts.—No dilatation of the ducts; no trace of ulceration of the mucous membrane of the gall-bladder or ducts. The ducts were followed to their smallest visible termination, and appeared quite healthy. The biliary ducts were patent. Adhesions.—There were no adhesions of the

liver to any of the surrounding parts, not even to the diaphragm. Peritoneum.—In every place clear and glistening, except over the liver, where it was thickened and matted together with the capsule. Stomach.—Apparently quite healthy, no marks. Intestines were removed, from stomach to rectum, and examined, but not slit open; they were healthy, no marks of ulcerations or congestion of the patches of Peyer. The rectum contained a quantity of bright yellow feculent matter. Spleen quite healthy and of fair size. Pancreas normal (rather firm). Kidneys apparently healthy, the right one, lying in fossa on right lower lobe of the liver, over the abscess; was quite sound; its capsule firm, no adhesions; their structure was continuous, and no trace of abscess discernible.

Uterus and Ovaries.—The uterus was congested, its mucous membrane gorged, and a little blood found in its cavity—pointing clearly to death having taken place during a menstrual period. The “os” was patent and admitted the tip of the finger; something like slight ulceration was visible. A polypus hung down from the ceiling of the uterus a little way into its cavity. No purulent matter was visible either in the uterus or vagina, which latter was a little congested, but otherwise quite healthy. In the left ovary was a series of cysts and small abscesses. The peritoneal covering was thick, and a loop of small intestine was bound to it, also some mesentery. In this matting of the intestine and ovary, traces of adventitious old adhesion bands were seen, placing beyond a doubt the long standing of the disease here. On dissecting the intestine carefully off the ovary, pus, or a fluid undistinguishably like it, oozed out from several little openings. The ovary was as large as a hen’s small egg. On cutting, it was seen to contain cysts filled with purulent-looking matter. Right ovary not so much diseased as the left. It contained one large cyst, which dissected cleanly, and contained about zii. of thick, pasty, white material, not unlike pus. This cyst appeared to be the ending of the Fallopian tube. Two or three small spherical bodies, as large as peas, turned out on section of both ovaries. They were firm, made up of laminated white structure, which was pearly and glistening, like spermaceti, and peeled into distinct layers like an onion.

On cutting across the veins on each side of the uterus not a drop of pus was found in them. One large vessel coming from the ovaries was filled with firm coagulum of fibrin. Fallopian tubes presented no unusual appearance, being almost impervious to a fine probe. Urinary bladder, healthy. Pott’s curvature.—The abscess of the liver was found to have no connexion whatever with this. The most careful dissection failed to trace anything here but firm bony ankylosis and normal tissue in every sense of the word. No traces of contusions were visible over the region of the liver, no broken ribs or ecchymosis. The contusions on each side of the spine were faintly seen on admission, and noth-

ing but the patient’s complaining would have caused them to be observed. All the tissues in their neighbourhood were free from disease or congestion.

DR. WALES said that all the symptoms recorded by Surgeon Whitla, and also the temperature, pointed to the disease as being typhoid fever.

Dr. Charles thought that a good deal might be said in favour of the abscess being pyæmic, especially as there were no ulcers in the intestines, or, again, the abscess might be idiopathic. An ulcer in the stomach sometimes caused pyæmic abscess of the liver, or the suppuration in the ovary might occasion blood poisoning; the only objection to the latter view being the absence of abscess in the lungs.

Dr. H. S. Purdon believed that a very common cause of abscess of the liver was ulceration of the bowels, especially in tropical countries (dysentery being the chief disease), and in which absorption takes place from the ulcers in the colon. The older authors held the opposite view, that the ulceration in the intestines was due to the vitiated bile from liver disease, and that the reason the colon was chiefly attacked was owing to the fæces being longer retained there.

Dr. McConnell said that it should be borne in mind that in pyæmia typhoid symptoms are always present.

The PRESIDENT remarked that the specimen struck him as a pyæmic abscess, and he believed that pyæmia could occur without a broken surface. The gall-stones showed that there was some previous hepatic mischief.

The President read a paper on pyæmia.

Ulster Medical Society. The Thirteenth Meeting was held on March 19th 1874.

The President in the chair. Members present Drs. MacCormac, Bolton, Smyth, McMurtry, Spedding, Whitla, Fagan, Charles, H. S. Purdon, J. W. Browne.

Dr. Charles introduced a patient with fracture of humerus.

Dr. MacCormac read a paper on “Strages Medicorum” (or exercise for the heart).

Paper:¹ “Neque imitare malos medicos qui in alienis morbis profitentur tenere se medicinæ scientiam, ipsi se curare non possunt.”—Cicero, Epistolæ ad Familiares.

THE word heart, at least in the English vernacular, has a two-fold signification, one applying to the physical heart through whose instrumentality the blood is constrained to circulate, the other to the moral heart, “the man within the breast,”—briefly, the sum of human feelings, duties, and affections. As the moral heart dwindles and declines by reason of insufficient scope and effort so, I maintain, does the physical.

I am aware of no treatise, ancient or modern, within the range of medical literature, in which, in short, no writer by whom, exercise as such for the heart

¹ [Dublin Journal of Medical Science, 1874, v58, p83.]

has been expressly recommended. And it is only after years of speculation and inquiry, coupled with the opportunities which hospitals and private practice confer, that the extreme, nay, the imperative necessity of exercise for the heart has come to command my most earnest attention.

The occasion, however, which perhaps more than anything else elicited this conclusion was the case of a medical man one, indeed, among many, who was an especial sufferer from the heart's irregular and excessive action with, however, entire absence of actual appreciable structural disease. Reflecting earnestly on the matter during the waking hours of the night, all at once it flashed upon my perceptions that the symptoms adverted to were to be ascribed were, in fact, alone ascribable, to simple inadequacy of the heart's action, owing to, and arising from, the insufficiency of general effort, that effort in which the heart, in common with every organ, is bound to take a part, and live.

I am only too well aware of the striving, anxious existence which so many medical men are required to lead. One's sympathies, in truth, are lacerated when one comes to think of those, the many, who within a comparatively recent period, have been snatched away by a condition vaguely termed "disease of the heart," yet not the less one in only too frequent instances, fatal to physician and patient alike. The number of those so cut off, were people only once made sufficiently aware of it, would indeed startle the least reflecting.

It is a common saying, and here at least one apposite enough, that we often cannot see the wood for the trees. For most true, indeed, it is that persons engaged in a daily routine of given action very frequently fail to discern facts which lie, as it were, at their feet, and before their very eyes. It is hard, in truth, to get out of the rut.

But why, it may be asked, regard being had to functional irregularity of the heart at least, why should we not endeavour to remedy a state of things so disastrous. It is easy to ask. First, if you care to do so, invite a lawyer to revise the code; a divine to change his creed. One will, perhaps, reply that the code is perfect; the other, that his creed is not fallible. But the doctors, why the doctors are mainly like the rest of the community, and do not, in general, care for change or inquiry until, at least, they know the reason why. In short, human nature is conservative, and, for the most part, dislikes nothing so much as novelty.

It might be imagined that the heart, in incessant, or nearly incessant action, as it is at all times, was exercised abundantly. But it is really far otherwise, for the ordinary cardiac action is virtually a passive one, needs, in fact, to be supplemented. Increased periodic effort, in reality, is needful, in order effectively to promote the circulation and æration of the blood. It is also further requisite, in respect of the integrity of the heart's action itself, requisite, in short, to prevent this

all important viscus from sinking into languor and relative inaction, as well as to equip it for any sudden encounter or unwonted demand upon its energies. Now, if not entirely unaware, we are too often, at least, almost entirely heedless as to the really pressing necessity there is for vigorous supplemental effort in aid of the ordinarily still and, as contrasted with its requirements, over passive life of the heart.

The malady, then, to which I would here desire especially to advert, if indeed malady it may be termed where structural change is not necessarily present is one, nevertheless, productive of much distress, and very often real danger. Fatty heart, weak heart, feeble heart, flaccid heart, conditions more or less concurrent, name them as you will, conditions attendant on our civilization, so esteemed, do not, however, much trouble navvies, sailors before the mast, common soldiers, or labourers afield. The derangement, as I have said, is for the most part functional, and yet is productive of greater suffering and potential risk than what in many cases attend actual structural cardiac disease itself. In a word, the action of the heart has become enfeebled, its action is no longer normal, but has become shabby and degenerate instead. Women, it is true, at least speaking of more dangerous extremes, are far from being exempt, but the causes or, at least, some of the causes, which conduct to weak heart are, on the whole, less common among them than among men. In any case, whatever may be alleged in respect of the relative liability of the sexes, I have no hesitation in affirming that too long sustained mental effort, coupled with insufficient bodily effort, and, therefore, insufficient heart's action, and inordinate personal indulgence, taken altogether, suffices fully to explain the greatly increased frequency of destructive functional cardiac insufficiency.

The literary classes, lawyers, clergymen, teachers, and others, are very far indeed from being exempt, but medical men, I have arrived at the conclusion, prove especial sufferers, to such an extent, indeed, as fully, I conceive, to justify the heading which I have selected. For a time, and so long as he remains young and active, trudging about on foot, and obliged to rough it a good deal, the "doctor" gets on well. The heart, like the rest of the economy, is constrained to exert itself, has no time, in short, to relax, and become fat and flabby. By-and-bye, however, the doctor gets into request, is borne about on wheels in his all too comfortably cushioned box, consumes highly azotised fare, drinks a generous glass of wine, but otherwise does no work, at least such work as nature requires and as a medical man, himself a victim, recently wrote to me, "comes to suffer for his sins of omission and commission accordingly."

It is, in fact, impossible, under such circumstances, that the heart should escape. This so important organ, failing adequate muscular effort, like the rest of the body, grows fatty, flabby, faint, and weak, until some

day, a greater strain being laid upon its energies than usual, nay, perhaps without any strain at all, it gives up work for ever. Possibly, nay, probably, there was no structural, at least no serious structural change whatever, no regurgitation, no aortic or mitral insufficiency, but, coddled and cockered to excess, the heart pretermitted effort, simply because it was no longer equal to effort. In strictness there was not much to do, but that much it had become unable to perform. Insufficient general action then leads to insufficient cardiac action, and insufficient cardiac action, in its turn and, in the long run, leads to death.

The especial case, one however out of many, already adverted to was that of a physician, who had been engaged in a treatise involving laborious inquiry and protracted research. He rose early, in fact at four in the morn, in order, as he hoped and believed, to gain time, and not to trench upon the daily routine of his professional duties, arranging notes, consulting a multitude of authors for long hours together, and that without partaking of food or refreshment of any kind. Locomotion in the way of his business was performed in a carriage or on horseback. As for foot exercise or other protracted bodily effort, there was little or none of it. The result, after this regimen had been pursued for some time, was the production and progressive increase of faltering in the heart's action. It was not, indeed, severe or distressing at first, but eventually it became both, until at last the anguish proved such as perforce to constrain a complete, or all but complete, abstention from all desk work. There then ensued a partial amendment, but on resuming literary effort the symptoms, as described, recurred, with fresh aggravation and increased persistence. In the street or on the highway, whether walking or riding, they often sufficed to bring the sufferer to a complete standstill, occasionally even the nights were passed without sleep, spent, indeed, in pacing up and down the apartment, or sitting on the bedside until it was time, so far as might be, to resume the business of the day. On one occasion there was a risk of drowning, the heart's action having become so irregular and distressing, while bathing in deep water, as to render it no longer possible to swim. Happily, the sufferer could float, and with the water awash with his face, he drifted with the tide towards the open sea, until his companions, wakening up at length to some dim perception of danger, put off in a boat, and enabled him to return.

Life, in fact, had grown burthensome, and the patient, doctor though he was, no longer knew exactly what to do. At last a little light became visible amid the darkness, and the first result of this new insight was to discontinue literary work, at least for the nonce, entirely. Relinquishing riding and driving as exclusive modes of conveyance, lengthy walks were taken, the lofty hills were clomb, the sea-shore was frequented, and daily recourse was had to the oar, the dumbbell, the

club, and other moderate gymnastic efforts. The sufferer, when in the country, would also descend from the saddle or the driving seat, and run a mile or a couple of miles at a stretch, as the horse trotted slowly along. In other respects, the appetite was left sharpset; the breakfast, however, was abundant, but the dinner was invariably sparing. At first, indeed, all this proved a little difficult, but by degrees nature accommodated herself to every restriction as persevered in, not only for months, but for years. The once so persistent and sadly worrying cardiac irregularity gradually, but completely, ceased, yielding place to a prolonged, and, it is believed and hoped, a lasting immunity. Late or early the labours of the desk are now pursued without a colour of inconvenience. No day, however, is permitted to pass without its complement of bodily effort, and, as for the food restrictions, they have long become habitual. In a word, a most distressing, not to say dangerous, infliction has disappeared, and the whilom sufferer, although no longer what would be esteemed young, goes through an amount of bodily and mental effort not very usual at any period of life.

The weak, the fatty, and the flabby heart, one condition or all, is, indeed, the especial malady of indolent persons. I speak of bodily indolence, in persons of easy circumstances and, commonly at least, it does not assail the hardworking, the abstinent, and the poor. Members of the medical profession, as already stated, so far at least as my observation extends, are peculiar victims. Many, alas, too many, are they beside whose couch I have sat who perished of it, while others there are who, to my cognizance, now labour under it. Writers on diseases of the heart are full of details of structural cardiac disease, while this so serious, because destructive, affection is left, I speak of weak and fatty heart, I do not say entirely, but comparatively, unheeded. One, for example, shall carefully examine a given heart, and discover no aortic or mitral insufficiency, no buzz, no bruit, nothing at least from a stethoscopic point of view, calculated to awaken serious solicitude, and yet the possessor of this heart peradventure shall perish suddenly. Exercise for the heart, setting forth its absolute indispensability, is the heading of no essay, the title of no book, at least as known to me; nevertheless, there is no subject whatever more deserving of careful consideration and attention. In respect of the treatment, I desire to be explicit. Every species of guarded prolonged muscular effort, as digging, hoeing, rowing, reaping, felling, chopping, ploughing, is useful, but, to those who labour under functional heart affection, walking, though not to excess, not too fast and not unduly far, over hilly unequal surfaces, swinging the arms, unembarrassed by bond or stay, in the open air, is the best of any. An hour before breakfast and an hour before dinner, one or both, are the preferable periods of the day. Exercise develops and strengthens the cardiac muscular fibres, ærates the blood, at the same time fat

is sparingly developed, and, coupled otherwise with cautious and abstinent habits, the heart's action becomes reliably even and, without defaillance, equal to all life's proper exigencies.

By this thoughtful, sparing, and cautious regimen, enough of everything and yet not too much, ne quid nimis, the heart no longer saddled, swaddled with useless fat, flabby or feeble, will be found, amid all the varying requirements of this complex, often trying existence, to discharge to admiration its daily allotted task. Living too fast, indeed, as some are fond of saying—why, we cannot live too fast, provided only we live nobly and well. An hour, or I shall say two hours, out of the twenty-four, is not too much, is it, to devote to open air life and effort, in order to promote the healthy action of the most vitally essential integer of our wondrous organism, the heart. Yes, indeed, he, qui ipsi sibi sapiens prodesse non quit, nequidquam sapit.¹

Robert Dill, Chairman

Case published under the title “Transactions of the Ulster Medical Society” in the Dublin Journal of Medical Science, 1874, v58, p73.

March 1874

Paper:² Dr. M'Crea exhibited a cigar-shaped calculus, which had been extruded from the bladder of a female. The calculus was originally about an inch and a half long, and three-eighths of an inch in diameter at its thickest part.

The woman had declined to submit to the removal of the calculus. One day she could not “pass water,” for which she took gin in repeated doses for two days. At last the force generated dislodged the stone from her urethra. It broke in falling, but the principal portion is one inch long.

She had invented the new operation of hydrostatic extrusion.

Fourteenth Meeting was held upon the 2nd April 1874.

Present, Dr. Dill, J. Fagan, J. J. Charles, J. W. Browne, Dr. Rankin.

Dr. J. W. Browne read notes of a case of puerperal convulsions.

Paper:³ DR. WALTON BROWNE brought under the notice of the Society a case of puerperal convulsions that had occurred in his dispensary practice. He believed that the point of interest in the case was that the convulsions, which were more than ordinarily severe, ceased immediately after puncturing the membranes, and allowing the liquor amnii to escape. He had tried various remedies, but they were unsuccessful.

PROFESSOR DILL remarked that bleeding in convulsions

had been too much set aside of late years, not only in this affection, but in other diseases. He thought that convulsions were due to one of the following conditions—1. Hyperæmia; 2. Anæmia; 3. Toxæmia. When the os uteri was rigid, bleeding should be resorted to. Braun, of Vienna, recommends benzoic acid and counter-irritation over the kidneys.

Dr. Fagan thought that the urine should have been examined in the early stage.

SURGEON RANKIN said that treatment directed to the kidneys in the early stage, in the case under notice, would not have been of any service.

DR. CHARLES stated that benzoic acid is converted into hippuric acid, which acts as a diuretic.

Dr. James Moore exhibited a fatty tumour which he had removed from the back of a man aged 45 years.

Also a scirrhous removed from the mammary gland of a man aged 74 years.

James Murray

Ulster Medical Society.

The President in the chair. Present Drs. Cuming, Purdon, William Browne, McCrea, Dill, McKeown.

The President proposed J. K. Houston M.D. as a member of the Society.

Ulster Medical Society. The Concluding Meeting of the present session was held on April 30th.

The President in the chair. Members present Drs. Fagan, H. S. Purdon, Charles, Rankin, D. Johnston.

John Knox Houston M.D. was balloted for [and] unanimously elected a member of the Society.

Surgeon Rankin gave the notes of a case of paralysis agitans treated by hypodermic arsenic.

Paper:¹ SURGEON RANKIN brought under the notice of the Society a case of paralysis agitans, occurring in a man aged seventy-two, by occupation a carpenter, and which disease he had treated by the hypodermic injection of arsenic. The patient, he said, first came under his care for bronchitis, he then complained of great and increasing tremor in both hands and arms. This lasted for some time. He could not even lift a cup of water to his mouth. Tonics were tried, which improved the general health, but had no effect on the shaking. About this time Mr. Rankin saw a notice in the Dublin Medical Journal regarding the hypodermic injection of arsenic in similar cases, and it occurred to him to give that remedy a trial. He made a solution of equal parts of water and the liquor arsenicalis, of which he injected subcutaneously into the neck 5 minims every second day, to commence with. After the third injection the patient was able to lift a tumblerful of water to his mouth, and could close both his hands without tremor. He complained after the second injection of tenderness

² [Dublin Journal of Medical Science, 1874, v58, p77.]

³ [Dublin Journal of Medical Science, 1874, v58, p81.]

¹ [Dublin Journal of Medical Science, 1874, v58, p82.]

of the conjunctiva of both eyes, showing that the arsenic was beginning rapidly to take effect. He can now (April) work at his employment. Whether the improvement will remain permanent or not it is difficult at present to say.

Dr. Charles asked what advantage the hypodermic injection of arsenic had over giving the medicine by the mouth.

DR. H. S. PURDON said that one objection he had to the hypodermic injection of arsenic (which he had tried in psoriasis) was, that it was apt to occasion little superficial abscesses; however, the remedy seemed to act more rapidly when administered subcutaneously. As for it (the Fowler's solution) not disordering the stomach when so given, he believed that if the compound spirit of lavender was left out in its preparation, and ordinary care used in its administration, derangement of the stomach was seldom likely to occur when the remedy was given by the mouth. For neuralgia and tremor, the hypodermic injection of caffeine had succeeded well.

Dr. Fagan introduced a patient with a rare affection of shoulder joint.

Dr. Charles read notes of a case of intussusception.

Case published under the title "Transactions of the Ulster Medical Society" in the Dublin Journal of Medical Science, 1874, v58, p73.

April 1874

Pruritus Vulvæ—DR. H. S. Purdon called attention to the disease known as pruritus vulvæ, or prurigo pudendalis. It was frequently due to irritation arising from uterine or bladder ailments. Sometimes ascarides in the rectum, especially in children, travelled into the vagina, causing the disease; and in such cases the irritation they produced often led to masturbation. Diabetes was another cause, the saccharine urine producing a fungoid growth, shewn by aphthæ, due to the presence of the fungus, the *oidium albicans*—the same growth that caused "thrush" in the mouth. In such cases sulphurous acid lotion, carbolic acid, and glycerin, or even borax, were useful. The tearing of the parts by the patient caused excoriations and an eczematous eruption, which had to be treated by nitrate of silver and astringents. Females were said to have miscarried from this form of pruritus. Pruritus of the anus was often associated with pruritus of the vulva, due to the same cause, viz., parasitic growths; the fact that both situations are naturally moist favours a vegetable growth.

Ulster Medical Society

Annual Meeting, November 4, 1874

Present, Dr. John Moore (President) in the chair, Drs. Stewart, McCrea, H. M. Johnston, H. S. Purdon, Fagan,

James Moore, J. W. Browne, Core, Spedding, and Charles.

Minutes of last Annual Meeting read and confirmed.

The President read the Annual Report of Council, when it was moved by Dr. Stewart and seconded by Dr. H. S. Purdon "That the report now read be adopted". (Carried.) The Office Bearers for the ensuing session were then selected.

President

Dr. Charles D. Purdon

Vice presidents

Dr. Stewart and H. S. Purdon

Council

Drs. McCrea, J. W. Browne, Spedding,
H. M. Johnson, Murney and Core

Hon. Treasurer

Dr. Fagan

Hon. Secretary

Dr. J. J. Charles

Dr. Stuart moved "That the best thanks of the meeting be given to Dr. Fagan, Treasurer, and to Dr. H. S. Purdon, Secretary, for their valuable services during the past session". Dr. Charles seconded the motion, which was carried unanimously.

The Treasurer's report having been read, Drs. Whitaker and Spedding were appointed Auditors.

Dr. James Moore having been called to the chair, it was moved by Dr. Stewart and seconded by Dr. Spedding "That Dr. John Moore, the retiring President, deserves the most cordial thanks of the Society for the efficient manner in which he discharged the duties of his office". (Passed by acclamation.)

REPORT OF COUNCIL

The Council in presenting to the Society their report for the past year regret to state that the attendance of members has to some extent fallen off, though in their opinion the papers read, the cases described, and the morbid specimens exhibited, were not of a less interesting character than those of preceding occasions.

The Society has to regret the loss, during the past year, of one of its oldest, most respected, and most influential members—Dr. William McGee, J.P. He was formerly President of the Society and Mayor of Belfast. From the high position he held in his profession as well as from his social standing among his fellow townsmen, he exerted a great influence on questions of sanitary science and others affecting the medical profession. He was beloved and respected by a wide circle of friends, and was followed to the grave by a large number of his professional brethren.

During the past session seven new members joined the society; and eighteen meetings were held, the average attendance at which was $7\frac{1}{2}$.

There were ten meetings of Council, and the atten-

dances of members was as follows:—Dr. John Moore 10; Dr. Stewart 7; Dr. Charles 7; Dr. H. S. Purdon 6; Dr. Fagan 5; Dr. Spedding 4; Dr. McCrea 3; Dr. Smith 1; Dr. Murney 1; Dr. McKeown 1; Dr. H. M. Johnston 1; and Dr. J. W. T. Smyth 0.

The Transactions of the Society were published in the *Dublin Monthly Journal of Medical Science*, and have since been reprinted and distributed among the members.

During the meeting of the British Association in Belfast, the members of the Association belonging to the medical profession were invited to a breakfast held in Thompson's Rooms, Donegall Place.

The visitors were:—Dr. William Carpenter, of London; Professor W. Wilde, of Dublin; Sir Duncan Gibb and Drs. Wood and Hare, of London; Professor Gluge, of Brussels; Dr. Michael Foster, of Cambridge; Dr. Cleland, of Galway; Professor Macalister, of Dublin; Dr. Muirhead, of Glasgow; Drs. Pye-Smith and Thomas C. Charles, of London; Dr. Caton, of Liverpool; Dr. Stewart, of Dublin; Dr. Corfield, of London; Professor Redfern and Dr. Thomas H. Purdon, of Belfast; Dr. O'Dwyer, of the 13th Regiment; Dr. Ashe, of Derry; and Dr. Grimshaw, of Dublin.

Thirty members of the Society were present:—Dr. John Moore, in the chair, Drs. C. D. Purdon, Dill, Seaton Reid, Ferguson, Henry MacCormac, Fagan, McCrea, McKeown, McConnell, H. S. Purdon, Brice Smyth, Cuming, Spedding.

After breakfast, claret and champagne were served. The President then proposed "The Queen" a toast which was heartily responded to. "The British Association and its Medical Members" was then drunk; it was responded to by Sir W. Wilde, Dr. Michael Foster, and Dr. Carpenter. "The Queen's University" was the next toast: Professors Cleland and Redfern responded. "Our Foreign Visitors" was proposed by Professor Cuming and responded to by Professor Gluge. "The Ulster Medical Society" was proposed by Dr. Carpenter and responded to by the President.

John Moore, Chairman.

Ulster Medical Society
Session 1874–1875
President Charles Nicholas Delacherois Purdon

ULSTER MEDICAL SOCIETY

SESSION 1874–75

**Ulster Medical Society. First Meeting
November 10, 1874**

Present, Dr. Charles D. Purdon (President) in the chair, Drs. Murney, Stewart, James Moore, John Moore, McCrea, McKeown, Bolton, Ball, Spedding, F. Beck, and J. J. Charles. Dr. Moss was introduced as a visitor by Dr. Stewart.

The President postponed the delivery of his opening address to the next meeting.

Dr. Murney exhibited a man on whose shoulder he had made several skin grafts, and he promised to give the members an opportunity of seeing the case again at a further stage of its progress.

W. Whitla, L.R.C.S. Ed. exhibited a large multi-locular cystic tumour of the ovary taken after death from a patient in hospital, and give full details of the history of the case.

Dr. James Moore then exhibited and give a brief account of a malignant tumour which he had removed from the thigh of a woman aged 62 years.

C. D. Purdon, Chairman
December 3, 1874

**Ulster Medical Society. Second Meeting
December 9, 1874**

Present, Dr. C. D. Purdon (President) in the chair, Drs. John Moore, Stewart, Fagan, J. W. Browne, Houston, Beck, H. M. Johnston, Spedding, Rankin, Whitla, and J. J. Charles.

The President delivered the opening address of the session on “The past medical charities of Belfast as compared with the present”.

Paper.¹ *Gentlemen, I thank you for the office to which you have elected me, as in so doing you have shown your desire to renew your acquaintance with old practitioners; and as one of that class, occupying the position I now hold, and standing in the place in which we are assembled, I cannot help taking a retrospective view of what has passed during my years of school, study, and practice here.*

The contemplation of these circumstances has so impressed me with the great changes that have taken place in this town amongst the medical practitioners and charities during the last fifty years, that I hope you

will not consider the time misspent if I bring before you this evening the medical charities that have existed here, and some of the eminent men who gave their time and services to benefit the inmates, and contrast them with the modern ones and the eminent practitioners of the present day.

When Belfast was a mere village in comparison with its present size—its inhabitants numbering some 17,000—there existed but very few charitable institutions, and also very few medical men; but they, though small in number, were remarkable for talent and philanthropy, as it was mainly owing to their exertions that this hospital owes its existence.

Need I mention the name of one of its founders, who, though, departed nearly fifty years, still lives in the memory of many of the seniors among you as a bright ornament of the profession—a man who, though commencing practice late in life, through the power of his intellect and energy of his character, soon rose to the highest eminence? This was Dr. Stephenson, sen., who at the beginning of his career was a Presbyterian clergyman, officiating in the Ards, but on account of theological disputes with the Synod, resigned his charge; and, notwithstanding that he was in middle life, commenced the study of medicine in Scotland, where he took his degree, then settled here, and was soon extensively engaged in practice, succeeding Dr. Halliday, sen., who was then retiring from active business.

Dr. Stephenson, being very benevolent, attended the poor in conjunction with the late Dr. M'Donnell, and in 1792 a dispensary was established, which relieved the Belfast Charitable Society and Infirmary from any further expenditure in the external department. In the year 1797, seeing that fever was being imported from Portpatrick, he was foremost in advocating a fever hospital, which was at once established according to his plan in conjunction with the dispensary, premises being taken in Berry-street, where, in the first six months, he attended seventy-three patients, and was so skilful in his treatment of fever that of the first sixty patients admitted not one died, and out of the seventy-three only three died.

These prompt measures having caused the fever to abate, the hospital was closed, and no institution of the kind existed until 1799, when a fever hospital and dispensary were established in West-street, where the poor received gratuitous advice. Dr. Stephenson was also one of the first physicians attached to the General Hospital when it was removed to this place. He continued to practise until advanced age compelled him to relinquish his profession, and died at a ripe age—over ninety years. He was always well known by his appearance and dress, as he was rather high in the shoulders, and always wore knee breeches and black stockings, white tie, &c., which was the usual dress of medical men at that time. He was brusque in manner, but uni-

¹ [The Irish Builder, 1875, v17, 1 January, p10. The Editor said “The address, though dealing with the subject of Medical Charities, furnishes many interesting items connected with the lives of popular professional men of historic note as also with the erection of buildings, with which the names of some of our eminent architects of the past are associated... For these reasons, and for others of a sanitary nature, we think the address, as a whole, will not be out of place in the pages of this journal.”]

formly kind to all who excited his sympathy. He died as he had lived, an honour to the profession, and was succeeded in his practice by his son, the late Dr. R. Stephenson, of whom we may say that his entire public life was devoted to upholding the dignity of the profession; and in him we found not only a kind friend as well as a skilful adviser, but also a fine advocate, and all of us who knew him had often reason to be glad that there was a Robert Stephenson.

The next eminent person attached to this institution was Dr. M'Donnell, who was also active in the foundation of this charity, and enjoyed an extensive practice amongst the higher classes. He was a learned and deeply-read practitioner, with a philosophical and inquiring turn of mind, often risking his life in the search for information. He, too, has passed away, after attaining an advanced age. In his appearance he was somewhat remarkable, clothed in drab-coloured knee-breeches and white stockings, white tie, &c., driving in an old gig hung on "C" springs, reading a book by the aid of a magnifying glass which he held in his hand, with his well-known servant, Mick, beside him. He used to boast that he never carried an umbrella, and exposed himself to all weather.

The next I have to mention belonging to this staff is Dr. S. S. Thompson, justly celebrated as a skilful and accomplished physician, who added to his medical pursuits the pleasing study of music, and so skilled was he in it that he was elected permanent president of the Anacreontic Society, a friend, and almost father, to many among us who are now the seniors of the profession. He was also found ready to assist in difficulty, professional or otherwise, and his conduct through life, both to his brethren and the public, was ever in accord with the motto on his coat of arms—"Honesty is the best policy." He, too, has passed away, leaving affectionate recollections of his worth.

Another talented physician attached to this hospital was A. G. Malcolm, whose whole mind was given to the study of his profession; but just as he was beginning to attain an eminence, which foreshadowed a distinguished future, such as he well deserved both by his contributions to the literature of his Profession and his skill in healing disease, he was cut off; but, though dead, he speaketh to the pupils of this institution in the exhibition which has been founded, and which bears his name. I forbear to mention the names of other medical men who have acted as physicians to Belfast charities, as we still enjoy the pleasure of their society, and the advantage of their skill, and I hope that we as practitioners, and the public as patients, may long continue in possession of that society and skill.

I will now draw your attention to another class of practitioners attached to local charities, the first of whom I will mention is one long since passed away, and the record of his talents and experience has been but dimly preserved and handed down—I mean Dr. Hal-

liday, sen., formerly an eminent medical man here, whose advice was sought in all quarters by rich and poor, high and low. He first came to Belfast as surgeon to the Cameronian Regiment, and his skill was so soon acknowledged that he left the army and settled here, becoming the consultant of the entire county, and was in such demand that he was able to fix his own remuneration of one guinea per mile. Of him it is said that he always attended a consultation in court dress, by way of sustaining the dignity of the profession, I suppose; but being too often called in only when the case had become hopeless, he used frequently to express his opinion of this neglect in his quaint way by saying, "I am like a huntsman, always in at the death."

He was succeeded in practice by Dr. Stephenson, sen., and his son, who, however, did not continue many years in the profession, being early confined to the house by disease. The next in order is Surgeon Comins, who practised in this town, besides holding the post of Deputy-Inspector General of the Forces, and, if my memory serves me rightly, he was also surgeon to the infirmary of the Belfast Charitable Society. He was the first in Belfast who performed an amputation of both legs at the same time, which was thought so extraordinary an operation as to be published far and wide in the newspapers. The sequel to the operation, consisting of the death of the patient, was, however, not noticed. It is said of him that, being of a money-making turn of mind, he kept a flock of ducks at the military hospital, which were fed on the poultices after the patients had quite done with them. These ducks he used to send to the market, but the public having discovered that something was rotten in the state of Denmark (or rather in the state of the ducks), the secret of their diet leaked out, and thenceforward as long as the doctor remained here, ducks were as a drug in the market.

Dr. Drennan also was one of the first attendants of the Belfast Charitable Society. He practised here for some time, and rose to eminence. A great deal of his time was devoted to this society, and I may mention that it was he who introduced inoculation in the north of Ireland. He was of retiring habits, an elegant scholar and poet, and the record of his professional attainments and work may be found in the transactions of this noble institution.

I will now turn to one who, being everything to me, it will, I trust, prove an apology for bringing him under your notice this evening. Of him I will only say that his abilities and character were recognised and appreciated by all who knew him. I need hardly mention the name of Henry Purdon, sen., formerly one of the first surgeons of this place. He came here as staff-surgeon, having charge of the military hospital. As he had great experience in foreign service, he soon became distinguished as a skilful operator, and was for a long time one of the surgeons at this hospital, as also to the Belfast Charitable Society. During his professional

Ulster Medical Society
Session 1874–1875
President Charles Nicholas Delacherois Purdon

career he was invariably the friend and adviser of his brethren, and, though he has long passed away, his place is supplied by his son, Dr. Purdon, once the surgeon of this institution, as well as the colleague of some who are still engaged within its walls; and now the father of the profession in the town.

Another celebrated man was Staff-Surgeon Forcade, who for a long time gave his services to the poor in this town. His skill in operating and in treating those under his care was well known and acknowledged by all. He, too, has passed away, and left but kindly recollections to those who knew and esteemed him. Another pillar of the profession was the late Surgeon D. Moore, who, after being employed in the Royal Navy during the war with Napoleon, settled in Belfast when peace was proclaimed, and gave the benefit of his great experience to the patients of this hospital as surgeon, to which he continued until advancing years caused him to resign his place to his son, Dr. James Moore, who combines in his person the skill of the surgeon with the talent of the painter; all he lacks is the taste of the poet. There is but one more of the many eminent men who were associated with this charity whom I will mention (for to speak of all as they deserve would occupy more time than we have at command), and that is the late Dr. J. M. Saunders, who was cut off in the prime of life, just as he was rising to great eminence in his profession, leaving a void in this place which it took a long time to fill; and still our remembrance of his thoughtful care of the sick, and his tenderness in treating and skill in prescribing and operating throw a halo around the memory of James Saunders. But having had enough of those gentlemen who gave their skill for the use of these institutions and the advancement of science, I will now speak of the institutions themselves.

In the middle of the last century, Belfast, through the intelligence and energy of its merchants, who laid the foundation of its present prosperity, began to be of commercial importance, which naturally attracted numbers of labouring classes as well as vagrants from all parts of the North, and these became so numerous as to demand the attention of the leading inhabitants of the town and adjoining country, a meeting of which gentlemen, consequently, was held in the "George" on the 20th day of August, 1752, to consider the question of building a poorhouse, hospital, and church, the necessity for which is shown by the following resolution, passed at a subsequent meeting:—"Resolved that, whereas a poorhouse and hospital are greatly wanted in Belfast, for the support of vast numbers of real objects of charity in this parish, for the employment of idle beggars who crowd to it from all parts of the North, and for the reception of infirm and diseased poor; and whereas the church of Belfast is old and ruinous, and not large enough to accommodate the parishioners, and to re-build and enlarge the same would be an expense grievous and unsupportable by the ordinary method of

public cesses. Now, in order to raise a sum of money to carry these good works into execution, the following scheme has been approved of by the principal inhabitants of said town and gentlemen of fortune in the neighbourhood who are friends to promote so laudable an undertaking."

This scheme was a lottery, by which they were to raise a certain sum of money, the tickets to be sold in the principal cities and towns of the empire; but as the scheme did not receive much encouragement in London, and the tickets were cried down, the committee sent over to London Messrs. Gregg and Getty, with the power of an attorney, "to promote the execution of the scheme and at the same time arrangements were made for obtaining subscriptions, that by their assistance the lottery might be carried out; and, in order to restore public confidence in the scheme, the following advertisement was inserted in the papers:—"Whereas it hath been maliciously reported that the Belfast charitable scheme was to be given up, the managers think proper to give this public notice that the same is without grounds, and that they have taken proper measures to carry the said scheme into effect." Notwithstanding this advertisement, the scheme was still decried in London, and legal proceedings had to be taken against purchasers to make them pay for their tickets.

At last a sum of money having been obtained, a committee was appointed for the purpose of drawing up a memorial for presentation to Lord Donegall, asking him to grant a piece of ground to the society. He having acceded to this request, plans were invited from parties in England and Scotland as well as Ireland, stating to them the sum to be laid out on the building for poorhouse and hospital as £3,000, which sum was found sufficient, as the inhabitants of the country round about furnished stone, sand, lime, and water gratis. The plans having been received, were exhibited in the market-house for the inspection of the gentlemen in charge of the undertaking and inhabitants. After considerable discussion, three of the plans were selected, and sent to Dublin to Mr. Cooley, who was to improve on them. Finally Mr. Cooley's plans were adopted for a poorhouse to accommodate 36 inmates, and an hospital to contain 24 beds.

The foundation-stone was laid on the 7th August, 1771 ("a day memorable for many glorious events in the history of this nation"), and five guineas were enclosed in it. The buildings, when finished, had, in addition to the hospital and poorhouse, assembly-rooms for the use of the townspeople and profit of the charity. About the 17th September, 1774, the hospital was opened for the admission of the sick, who were admitted from the several districts into which the town was divided. Foreigners also were admitted into the infirmary "on the consideration that they pay for their support and medicine." The physicians and surgeons, being asked if they would be pleased to attend such for-

eigners gratis, made reply, "As we have already contributed by subscription to your charitable institutions, and offered gratuitously our attendance on the indigent sick of the town and parish of Belfast, we cannot at present undertake to enter into foreign engagements, the extent of which might involve us in a business very different from that which we intended when our services were offered to your society."

In addition to receiving the sick into the infirmary, an extern department was established, at which a physician and surgeon attended each Tuesday and Saturday, for the purpose of giving advice and assistance to such persons as came within the rules of the society. Wards were also allotted for the treatment of lunatics; and we find, from an entry in the committee-book, that one of the lunatics was to be handcuffed and chained by the leg. The physician and surgeon attended by rotation three months at a time. Drs. Stephenson, Ferguson, Halliday sen., Apaley, Halliday jun., Drennan, and Bankhead; Messrs. Campbell, Bowen, Comyns, M'Clurney, Marshall, Purdon, White, M'Clelland, Anderson, Gelston, and Montgomery, were some of the first attendants of this noble institution.

I may here mention that in this establishment were made the first trials of inoculation and vaccination in the North of Ireland, as may be seen by the following resolution, passed by the committee on 4th May, 1782:—"Resolved unanimously, that the thanks of this committee be given to Dr. Drennan for his introduction of the plan of inoculation, which has been adopted by the society, and that Mr. Bristow be requested to notify to the public the adoption of the plan." The plan was considered of such value that on the 1st June, 1782, we find the committee passing this resolution:—"Resolved, that thanks be returned to Dr. Drennan in the public papers for the scheme of inoculation introduced by him into the house, and that Mr. Crombie do wait on him and acquaint him with the resolution; and that he send it to the papers, provided the doctor doth not oppose it." Vaccination was tried by Dr. Halliday jun., as the entry in the committee-book, 29th of March, 1800, attests:—"Dr. Halliday jun. attended, and proposed that the children of the house, or as many of them as had not the small-pox, may be inoculated for the cow-pox, upon the assurance that it is not infectious; that it is an easier disorder than the small-pox, as certified by a number of most respectable physicians in England. Resolved, that the experiment be tried on a few of the children in the house, provided that the parents of the children freely consent thereto."

For many years this society continued the only charity in the town; but gradually other institutions became established, which relieved its expenditure and enabled the committee to restrict their admissions to the poor and diseased; and within the last few years, through the munificence of the late John Charters and Edward Benn, new wings have been built for the

accommodation of children and the sick, and at present there exist four commodious wards for adults and two for children, containing upwards of forty beds for patients labouring under chronic diseases. These are under the care of Dr. Ferguson and myself.

The dispensary was established in 1792, thereby enabling the Belfast Charitable Society to close its extern department, as by its means the poor were attended at their own residences. It rapidly became popular, and in the first four years and four months 2,406 patients received advice and assistance; it has been developed by the Poor Laws into two extensive dispensaries, attended by seven medical gentlemen.

The fever hospital, as before stated, was first established in Berry-street, being attached to the dispensary, with which it continued to be associated for years, and proved most effectual in checking the epidemic at that time raging in Belfast, on the abatement of which fever it was closed; and no hospital for infectious diseases existed until 1799, when it was re-opened in West-street, in charge of two physicians (increased in June, 1819, to three), two consulting physicians, two surgeons, and an apothecary.

Finally, on the 18th August, 1817, the hospital was removed to the present building in Frederick-street, when four physicians and four surgeons were appointed to attend regularly. Of late years it has been enlarged by the liberal donations of the late John Charters and Sinclair K. Mulholland, who have built two large wings; so that now it may be said to rank foremost among the charities not only of Belfast, but of the North of Ireland.

The Lying-in Hospital was opened in 1794, and supported by subscriptions from ladies in the town and county. About forty-live years ago it was removed from its original site in Donegall-street to its present position. Its attendants are too well known and remembered to require any mention on my part. However, I may say that it is at present in charge of Drs. Smith and Burden, the latter of whom has retired from active practice to enjoy the rest so well earned by his attention to suffering humanity.

The Chapel-lane Dispensary was opened in 1827, for treating especially diseases of the eye, and, through the talent and exertions of its two medical attendants, became thronged with patients. It was at last closed, after continuing several years, soon to be succeeded by a similar institution, which continues to the present day.

These that I have mentioned were the medical charities which existed when Belfast was but small in comparison with its present importance. As population increased, charitable institutions sprang up, gaining for Belfast a reputation for benevolence which extends over the entire kingdom. The first in order of these more modern institutions is the asylum for the treatment of the insane, established in 1829, and at present

Ulster Medical Society
Session 1874–1875
President Charles Nicholas Delacherois Purdon

under the care of a gentleman whose reputation is more than European, Dr. Henry MacCormac, consulting physician to the asylum, who is most ably assisted by the resident medical officer. Dr. Stewart, considered one of the first physicians in Ireland for ministering to a mind diseased.

Next comes the Ophthalmic Hospital, built by the benevolence of a lady whose name is enshrined in the records of almost every local charity; and I am sure when I mention Lady Johnson you will all join in the wish that she may long live to witness the good results that spring from her philanthropy. This hospital is under the care of the Drs. Browne, who are well known to you all.

Another institution which has grown to colossal proportions is the hospital for infectious and contagious diseases, adjoining the Union Workhouse, and under the Poor Law management, the principal medical officer of which, Dr. J. S. Reid, is so well known and appreciated that he requires from me nothing further than the mention of his name.

An hospital for cutaneous diseases, established in 1864 as a dispensary, is now, through the donations of the late Edward Benn, about to be removed from its present site to a new and handsome building in Glenravel-street, beside another institution founded by the same large-hearted man, the Ulster Hospital for Diseases of the Eye, Ear, and Throat; these two are respectively attended by Dr. H. S. Purdon and Dr. McKeown.

Still another hospital, founded by Mr. Benn, is the Samaritan, for diseases of women and children. It is under the care of Dr. M'Mordie; in addition to which we have two other hospitals for children, which are, through their attendants, contributing much to alleviate the suffering of the young; and, finally, there is just now established, through the benevolence of the late Samuel Martin, an hospital for children labouring under chronic diseases. It is built in a healthy locality near Belfast, on ground purchased by him, and given, with the building, to the committee of the Belfast General Hospital.

Having now mentioned the old and new medical charities of Belfast—all of which are, under the judicious care of their several attendants, labouring to check disease, relieve suffering, and promote health,—it only remains for me to conclude my brief sketch of their history with the hope that the gentlemen who gave their time and skill to them may attain the position and reward their merit deserves, and continue to enjoy the respect and affection of the public when he who now addresses you has in his turn passed away.

Dr. John Moore then moved that the best thanks of the meeting be given to Dr. Purdon for his very interesting address. The motion was seconded by Dr. Stewart and carried by acclamation.

H. W. Johnson L.R.C.S.I. next moved that Dr. Purdon be requested to allow his address to be published in the medical journals and in the local newspapers. Dr. Stewart seconded the motion, which was carried.

John Moore, Chairman
December 16, 1874

**Ulster Medical Society. Third Meeting
December 16, 1874**

Present, Dr. Charles D. Purdon (President) in the chair, Drs. Stewart, John Moore, H. S. Purdon, Barnett, McKeown, J. W. Browne, Houston, Core, Fagan, Bolton, Whitla, and J. J. Charles. Dr. McKenzie was introduced by Dr. Houston as a visitor.

W. A. McKeown M.D. exhibited a patient in whom he had performed a small iridectomy with good results.

J. J. Charles M.D. exhibited and described a recent specimen of necrosis of the jaw from phosphorus. The patient was a female aged 28 years, and had worked in a Belfast Match Manufactory for several years.

J. K. Houston M.D. read an able paper on necrosis of the cranial bones, and detailed the history of a case he had seen in the Union Infirmary.

He exhibited the necrosed frontal bone, and, from the appearance of it and the soft parts which surrounded it, he inferred, in accordance with Virchow's views, that the necrosis was the result of the syphilitic virus, though there was no history of such.

Some of the members coincided with Dr. Houston's opinion, but others thought it possible that the necrosis might have a strumous or even a local origin.

Paper:¹ THIS affection is almost always set down as being of syphilitic origin. Certainly, in the great majority of cases, this is true; however, I cannot doubt that scrofula more frequently determines necrosis and exfoliation of the cranial bones than is supposed.

The correct diagnosis of these cases is of great importance, as upon it depends the prognosis, whether hopeful or otherwise. When the previous history throws no light whatever on the case, and when the nature of the disease is not suspected by the patient, it is especially difficult to make a safe diagnosis; and the grounds upon which this may be accomplished are worthy of careful consideration. To Virchow, perhaps, the most careful investigation of the changes which take place in connexion with syphilitic deposit in bone and periosteum is due; and from the researches of that eminent author we are enabled to discern such marks and characteristics as shall lead us to determine, from the nature of the lesion, per se, whether it be of syphilitic or strumous origin.

All the changes which occur in bones or periosteum affected with syphilis have their starting point in the same pathological phenomenon, namely, a deposit of

¹ [1875 *Dublin Journal of Medical Science*, v59, p64.]

syphilitic lymph or syphilomatous matter, a substance consisting of cells and nuclei. This deposit occurs between the periosteum and the bone, in the medullary cavity, and in the Haversian canals and lacunae. In the case of the skull, it is laid down either underneath the pericranium, in the diploë, in the Haversian canals, or between the bone and dura mater.

Now it is upon the changes which take place in this material that all the subsequent characters which the disease assumes depend. If this lymph is of a firm or plastic character, then hard nodes, exostosis, thickening, and hypertrophy of the bone result. If, on the other hand, it is of the soft variety, with a tendency to break down and disintegrate, then ulceration, caries, and necrosis ensue.

Suppose we have a case of necrosis attacking the bones of the skull, how are we to determine, apart from the history of the case, whether its nature is syphilitic or strumous?

In the first place, Virchow lays it down, as a rule, that syphilitic necrosis is essentially a dry one, that is to say, it is not attended with suppuration. It seems probable that, after the syphilitic matter has done its work in separating from the bone both pericranium and dura mater, in a case where both tables are affected, that it is then disintegrated and re-absorbed, leaving the affected portion of bone dry and exposed. While these changes are occurring on the surface and underneath the bone, the matter which had been deposited in the Haversian canals and diploë also becomes disintegrated and undergoes absorption, forming carious spots in the necrosed portion, which give it a characteristic worm-eaten appearance. In the second place, the mode of separation of the sequestrum is very characteristic in syphilitic cases. A formative process occurs around the dead portion. A thin, vascular substance, according to Virchow, is first formed round the circumference of the diseased spot, and this subsequently undergoes ossification, and so the thickness and density of the edge of the living bone are increased. A process of this kind is never observed in scrofula. In scrofula the Haversian canals and lacunæ of the living bone around the dead portion are, indeed, found enlarged and numerous, and filled with a lowly organised lymph, showing a marked tendency to suppuration; but no true marginal ossification occurs. According to Goodsir, Küss, and Virchow, it is by the production of this pus, in cases of scrofula, that the dead bone is separated and floated off.

The following case will serve to illustrate some of the distinctive characters mentioned in this brief outline, and it is especially interesting, inasmuch as the history gives us little or no information regarding its nature.

Mary Duffy, aged thirty-eight, came under my care in the Union Infirmary, on the 15th of March, 1874. She was suffering from necrosis of the bones of the

skull. Her family history is the following;—Her father died of pulmonary consumption, and her mother is living and healthy. Ages not known. Had three brothers and one sister. The sister died at the age of seven years from consumption, and one of her brothers, aged four, died from the same affection.

She states that she was married when eighteen years of age, and that her husband is dead. The cause of his death is stated to have been disease of the liver, and ascites. She has had six children, five of whom are living and one dead. The child died at the age of three months, from gradual wasting or marasmus. Those living are all healthy. The first child was born a year and six months after marriage, and she never had an abortion. Such, then, is the family history.

And, now, we come to consider the history of the disease itself. She began to complain about seven years ago, and then, for the first time, fell into delicate health. She remembers no serious illness from which she suffered up till that date. Severe shooting pains then began to be experienced over the crown of the head, and these lasted for nearly one year. Then the left side of the neck became painful, and soon a soft, fluctuating tumour was noticed, which quickly broke and discharged, and that before any swelling was observed upon the scalp. The deep and excavated opening produced in the neck did not heal up for a long time, the ulceration process extending in one direction while the sore healed in another. The original tumour was anterior to the sternomastoid muscle, and near to the angle of the jaw, and the cicatrix extends from that point down the whole length of the muscle, and along the surface of the clavicle to its inner extremity.

A tumour was next observed over the right parietal bone, which assumed the size of a large marble before the skin ulcerated over it. From the opening over this tumour a small piece of bone was discharged, about four years ago. About two years ago a lump was observed high on the frontal bone. This remained stationary for a year or so, still, however, discharging a little watery fluid from very small openings. These tumours were all painful, the pains being subject to exacerbations at night. During August, 1873, she states that the frontal bone was first noticed getting bare. When she came under my care, she was in an extremely cachectic condition, pulse frequent, and very feeble, and a large portion of the frontal bone exposed and dry. There were three other ulcers over the upper part of the right parietal, the base of each showing a piece of dead bone. Very little suppuration was observed.

As she was suffering a good deal from pain and sleeplessness, I ordered a 2-grain opium pill every night at bed-time, and prescribed for her a mixture, consisting of equal parts of the syrup of the iodide of iron and compound tincture of cinchona, and of this she was to take a teaspoonful three times daily, after meals. Her diet included one egg, half a pound of beef-steak, and

Ulster Medical Society
Session 1874-1875
President Charles Nicholas Delacherois Purdon

three pints of sweetmilk daily. Soon signs of great improvement began to manifest themselves, and with these separation of the dead bone commenced. The piece of the frontal which necrosed measured four and a half inches by three inches, and consisted of both tables of the skull. In the bottom of the very large ulcer which remained, the brain could be seen and felt pulsating, separated from the external air by the membranes and dura mater, the latter being covered, however, by very abundant and healthy granulations. Around the sore the living bone was thickened and formed a very prominent ridge. This ulcer rapidly healed up, and a tolerably firm cicatrix was produced. From the openings over the parietal bone several pieces of the external plate were discharged. I saw this patient again on the 6th of October, and she was then walking about, and apparently in excellent health, having improved exceedingly in flesh and colour. She stated, however, that the sores on the side of the head had not yet healed up completely.

In considering this case, we are constrained to believe that the syphilitic poison alone produced the varied lesions here present, although the history, family or otherwise, sheds little light upon the subject. There seems, however, to have been a hereditary predisposition to consumption in her family, and whether the phthisis of her father or the liver disease of her husband had a syphilitic origin or not remains an important question.

In reviewing the facts of the case, as we have them before us, there are several points which claim our attention. And first of all the age at which disease commenced. This, according to the woman's own statement, was over thirty years.

Now, we know that the first manifestations of scrofula are extremely rare after thirty years have been attained, whereas tertiary syphilitic lesions are much more frequently met with after this period of life than before it. Then we have an account of a peculiar solitary tumour occurring in the neck, which, from its nature and form of cicatrix, we cannot but regard as a soft, cellular node. With respect to the disease in the bones, we note, particularly, that it was attended with little suppuration, that we have distinct evidence of those changes, both in the living bone and in the sequestrum, so ably investigated and figured by Virchow, and so characteristic of the presence of the syphilitic as distinguished from the scrofulous element.

Dr. Houston then exhibited the specimen.

DR. J. MOORE congratulated Dr. Houston on his first paper being such an able one. He coincided with him in regarding the necrosis in his case as of syphilitic origin.

Dr. J. W. BROWNE stated that, some years ago, he saw in hospital, under his father's care, a case in which "dry" necrosis of the frontal and parietal bones occurred in a young man, from a fall on the vertex, though he had no history of syphilis.

Dr. J. Fagan thought the necrosis might have been caused by an injury inflicted on the head when the patient was unconscious, perhaps from drink; and, accordingly, she would afterwards have no recollection of the occurrence when stating her history.

DR. J. J. CHARLES said the necrosis was most probably syphilitic, but he did not consider the facts which had been adduced by Dr. Houston sufficient to make the diagnosis a matter of certainty, more especially as the history of the case pointed distinctly to struma as the cause.

He thought a comparatively slight blow might produce necrosis in a strumous individual. He believed Virchow's views on this subject had not been sufficiently corroborated to place them beyond question. Indeed, he regarded it as very difficult, if not impossible, to state dogmatically, from the appearances of the parts alone, whether the disease was due to syphilis, struma, or a local injury.

The PRESIDENT coincided with Dr. Houston's opinion as to the origin of the necrosis. He referred to the case of a young man in whom necrosis of the bones of the cranial vertex resulted from struma.

C. D. Purdon, Chairman
December 30, 1874

**Ulster Medical Society. Fourth Meeting
December 30, 1874**

Present, Dr. Charles D. Purdon (President) in the chair, Drs. J. W. Browne, Fagan, J. J. Charles, and James Moore.

J. Fagan L.R.C.S.I. introduced a patient on whom he had performed Syme's amputation and exhibited the parts removed. He related the history of the case and at the same time denounced the use of the gouge in the treatment of caries.

One or two of the members present took exception to some of the principles he had enunciated, and considered the gouge very useful in suitable cases.

Paper:¹ THERE are some features in the case which I have just now presented to you, Mr. President, which I consider sufficiently interesting to induce me to lay the particulars of it before this Society:—

R. M'C., aged eleven years, was admitted on the 24th February, 1874, under my care, to the Belfast Hospital for Sick Children. He suffered from chronic sub-acute inflammation of ankle-joint and tarsal bones of left foot, which presented the characteristic appearances found in such affections. The contour of the joint was destroyed by the inflammatory thickening of the surrounding tissues, the integument glazed, and here and there of a purplish colour; three or four sinuses gave out an unhealthy discharge, one of which led down to a piece of necrosed bone on the back of the astragalus.

¹ [1875 Dublin Journal of Medical Science, v59, p257.]

The history I got from the lad was, that about a year previously, while running on the street, he fell, and knocked his ankle against the corner of the curbstone; he suffered great pain at the time, and in a few days had to take to his bed, where he remained for some weeks. After a time he began to walk on it, but it still kept tender, and a couple of months before I saw him it began to assume the appearance it had on admission.

After keeping him in hospital for about five weeks, without much benefit from the treatment employed, I determined (with the concurrence of my colleagues) on removing the piece of necrosed bone; and accordingly, on the 2nd March, after applying Esmarch's elastic band, and putting him under chloroform, I made a deep incision, about one inch and a quarter long, over the necrosed bone. The parts were perfectly bloodless, but a clear serous fluid oozed in pretty large quantity from the morbidly thickened tissues; I then applied the gouge, and removed what I considered necessary; in doing so I felt the bone very soft and friable. The wound was then washed out with a weak solution of carbolic acid, a pledget of lint left in it, and cold lotion applied. The next day the pain in the foot was intense. He got an opiate, and had water dressing applied. The edges of the wound now began to gape and look unhealthy, and in a few days began to slough; charcoal poultices were applied, and he got his opiate three times daily.

The sixth day after the operation he had a rigor, the foot became enormously swollen and inflamed, and an abscess pointed anterior to the external malleolus, which I opened, giving exit to a large quantity of purulent matter. This only wrought temporary relief. The foot was still exquisitely painful to the touch; large exuberant granulations, which bled freely on the slightest provocation, filled up the wounds, and an ichorous discharge, filled with fat globules, kept constantly oozing from them. As he now began to suffer from hectic, loss of appetite, and sleeplessness, I considered it necessary to remove the foot, but the mother not consenting to the operation the boy was taken home. After keeping him for about a fortnight she took him back again, and on the 25th May I performed Syme's amputation, assisted by my colleague, Dr. Brice Smyth, and our consulting surgeon, Dr. Browne. There was some oozing through the dressings, but not sufficient to cause any alarm; during the day he took plenty of milk, and slept well that night. I put him on the following mixture, which I am in the habit of using after operations:—

Bicarbonate of soda, 180 grains.

Dandelion juice, 4 drachms.

Water to 8 ounces. Mix.

Sign. No. 1.

Sulphate of quinine, 8 grains.

Tartaric acid, 120 grains.

Water to 4 ounces. Mix.

Sign. No. 2.

Two tablespoonfuls of No. 1 to be taken with one of No. 2 during effervescence.

I find this mixture to be extremely grateful to the patient, while its febrifuge properties I believe to be most beneficial at the time. With the taking of it the temperature and pulse were lowered, the tongue began to clean, and the bowels were gently acted on.

On the third day after the operation I removed the dressings; the wound looked healthy; there was slight discharge of healthy pus; after being well syringed with a solution of carbolic acid the stump was again dressed as at first. This process was gone through daily for about three weeks.

At the end of a fortnight the ligatures came away, and new skin began to bridge over the wound here and there. In three weeks the wound was healed over except at either extremity, where there was a pretty free discharge of pus oozing through exuberant granulations. I began to touch these with nitrate of silver, and applied pressure to them by means of wet strips of lint. After a short time they were very much improved, and he left the hospital a little over a month after the operation.

There are several points in this case, Mr. President, that to my mind are of some interest, and well worthy of consideration. The first is the propriety of interfering by operative procedure; and, if such be considered advisable, what are the next means to be adopted?

In this case the disease was of considerable standing, the inflammation set up at first by the violence of the fall in the synovial lining of the joints, spread, and involved the bone tissue. If properly treated at first, the result in all probability would not have followed, but circumstances were not in the boy's favour; he was poor and ill-cared for; and had he even got the proper advice, he had not the means of carrying it into effect.

Now I believe that in such affections as the one I have just described, and indeed in all chronic diseases of bones and joints, our line of procedure must be very much influenced by the circumstances of individual cases, and what might be considered injudicious and bad practice in one set of cases would be the best in another.

In cases similar to the one under consideration I believe we are justified in resorting to operative means, after giving a fair trial to a milder line of treatment, and such I consider in its true sense "conservative surgery." The course usually taken by such cases is, that after spending a considerable time in one hospital or another—in some cases, perhaps, with benefit—they go home for a time, only to return again with the disease more extended, and demanding greater sacrifice of parts than if operated on in the first instance. Among patients belonging to the more favoured classes of society such a course of practice, for obvious reasons, should be the exception.

In considering the means to be adopted when resolved on interfering, let me say that had I a similar

case again under my care I would not follow the same line of treatment. The operation of gouging diseased bone is, I think, too lightly recommended, and from what I have seen of it in the practice of others, and experienced in my own, I venture to hope that in course of time the museum will be considered a fitter place for the gouge than in the hands of the surgeon. I look on the operation as at once unsatisfactory, clumsy, and unscientific, possessing few redeeming features, but a great many to condemn it.

As usually performed it is a process of digging in the dark, there is no precision in it, and if one succeeds in his object of removing the diseased part it is generally at the expense of a much larger portion that very soon dies; or if, as in the case under consideration, the disease be seated in one of the short bones, the destruction of one or more in its neighbourhood.

Some will say that this wholesale condemnation of the gouge is not warranted, seeing that it is still in such general use by the most distinguished surgeons, and that there are certain localities where disease is seated in bones that cannot be reached so effectually by any other means.

I grant that cases do now and then occur requiring the use of the gouge, but I hope to see such improvements in surgical appliances that diseases of bones will be dealt with with the same precision as those in the softer structures, and that when mechanical means fail medicinal applications will come to the aid of the surgeon, and will enable him to lay aside so clumsy and unscientific an instrument.

There were a few other points in this case, Mr. President, that struck me as interesting. You will observe by looking at the parts removed that the lower ends of the tibia and fibula were in a highly inflammatory state, and, notwithstanding, the case progressed most favourably after the great exciting cause was removed.

The flabby granulations at the extremities of the wound, and the formation of several small abscesses about the stump, resulted from the breaking down of the unhealthy pulpy tissue that remained in the flap after the amputation. As much as possible of this substance should, I believe, be removed at the time of the operation.

In performing the operation there are two points that specially claim the attention of the operator, and which, if carefully looked to, will prevent that unpleasant and comparatively frequent result—sloughing of the flap. The first is, when making the incision across the sole of the foot, after entering your knife over the inner malleolus, to give it a sweep forward, and by this means preserve as much as possible of the plantar vessels; the next is, when reflecting the heel flap, to keep as close to the bone as possible—in fact, to scrape the tissues from the bone, and by this means the small muscular branches are preserved intact. I had occasion to tie but two vessels, the anterior tibial and peroneal, and

although the posterior tibial was visibly pulsating on the face of the flap, I could not make out its cut end, and did not like to disturb the parts looking for it when there was no hæmorrhage.

This fact is a proof of how simply sometimes a large artery can be sealed up, and so far advocates the method of torsion which is now getting into such deserved repute. The stump is now, as you have seen, in a condition to bear nearly the whole weight of the body, and with a properly constructed boot the boy will experience comparatively little inconvenience from the loss of the foot.

JAMES MOORE, M.D., said the stump they had just seen was an excellent one, and reflected credit on the operator. He did not approve of the gouge unless in exceptional instances.

J. J. CHARLES, M.D., thought the case before them was one of caries rather than of necrosis. He could not agree with the reader of the paper in his universal condemnation of the gouge. He believed the best surgeons would give it a trial before proceeding to amputate the foot—more especially if the patient was of a healthy constitution, and the caries confined to a limited area, say one of the tarsal bones. He thought it a good rule, in such cases, to expose the diseased part fully by free incisions.

Not to be hypercritical, he might mention that some surgeons would have preferred in this case excision of the astragalus, or of the ankle-joint, or Pirogoff's operation, since the os calcis was quite healthy. But, under all the circumstances, perhaps Syme's operation was the best.

The PRESIDENT stated that there are cases in which the gouge is the most judicious plan of treatment for caries. He referred to Mr. Solly's opinion in favour of the use of the gouge.

J. J. Charles M.D. exhibited a recent specimen of gangrene of the lower lobe of the left lung, the result of pneumonia in a cachectic constitution.

He also showed a specimen of extensive calcification of the mitral valve of the heart, and give details of the history of the case.

Paper:¹ Dr. Charles exhibited several interesting specimens which he obtained from the Queen's College Anatomical Rooms.

1. Gangrene of the Lung.—The disease in this specimen was confined to the lower lobe of the left lung. In it there was a cavity large enough to contain a body four inches in diameter; and suspended in its interior, in a sanious liquid, was a shreddy, tinder-like substance, of a dark greenish colour, and of a sour, unpleasant odour. On examination the gangrenous mass was shown to consist chiefly of the elastic fibres of the lung. The wall of the cavity was thick, firm, and composed of white

¹ [Dublin Journal of Medical Science, 1875, v60, p72.]

fibrous tissue, which formed an efficient boundary for the diseased structures, and separated them entirely from the comparatively healthy lung around. Pneumonia and extensive pleuritis existed on both sides of the chest.

History.—T. R., forty-four years of age, and of a broken-down constitution. On admission into hospital November 5, 1874, he complained of a slight cough, with dark sputa. The signs and symptoms of pneumonia increased in violence, and the sputa came to possess a foetid odour. His strength gradually gave way, notwithstanding the use of stimulants and the application of blisters. Death occurred after he had been eleven days in hospital.

2. Extensive Calcification of the Mitral Valve of the Heart.—In this specimen there was a ring of calcareous matter along the line of attachment of the mitral valve. For the most part the calcareous material was covered by endocardium, but in some places it formed sharp projections into the left ventricle. There was hypertrophy, with dilatation of both sides of the heart.

History.—J. M., aged sixty-five, received into hospital Oct. 8, 1874, in a weak state. His condition then was:—Face livid, with ascites and œdema of the limbs; considerable dyspnoea, but scarcely any cough; urine 1032, with some albumen and a large quantity of urates; systolic basic and apex murmurs. He seems to have derived only temporary relief from treatment, and he died sixteen days after admission into hospital.

3. Dropsy of the Fallopian Tubes.—This specimen was removed from the body of an unimpregnated female, who was forty years of age, and died from bilateral pneumonia. The uterus was small (four inches by three), and the os would only admit a probe. The mucous membrane was congested near the entrance of the Fallopian tubes, and beneath it, about the middle of the posterior wall, was a fibrous tumour of the size of a pea. The cervix was long, and contained a colloid liquid. The arteries were larger and more tortuous on the right side than on the left.

The Fallopian Tubes.—Both tubes were distended at their distal extremities to form cyst-like tumours, which were filled with a thin colloid liquid. The inner and outer ends of the tubes were occluded, owing to a thickening and folding of the mucous membrane, probably from inflammation.

The right tube was seven inches long, and the cyst-like dilatation two inches long and one broad.

The left tube was five inches long, and more contracted at certain parts than the right, and its outer distended portion was three inches long and one inch and a half broad, and closely attached to the ovary.

The right ovary was nearly normal in size, but its glandular portion was pale and atrophied.

The left ovary almost normal.

History.—No history of any symptoms having been referred to the diseased organs could be discovered.

Remark.—In this case both Fallopian tubes were nearly equally affected. This, according to Graily Hewitt,¹ is the rule.

4. Fibrous Tumours of the Uterus, with Cysts of the Cervix Uteri.—The uterus was taken from the body of a female who was sixty years of age, and died from “the decay of nature.” It was dragged down to the left side, so that the right Fallopian tube was half an inch higher than the left. This displacement was, no doubt, due to the adhesion of the left Fallopian tube to the lower part of the body of the uterus, as well as to the presence of a large tumour on the same side. The body of the uterus was thin, and five inches long. A fibrous tumour (intra-mural) occupied the fundus, and measured two inches from side to side, one inch from above downwards, and half an inch from before backwards. This growth was surrounded by a capsule of fibrous tissue, to which it was but loosely connected, at its lower and back part, by a very fine pedicle of blood-vessels and muscular tissue. Two other tumours (sub-mucous), of the size of peas, lay on the left side of the fundus, near the entrance of the Fallopian tube. In the Broad ligament, one inch to the right of the uterus and above the Fallopian tube, there was another tumour (sub-peritoneal), as large as an almond; and in the left half of this ligament, near the rectum, was a fifth, which was attached to the lower part of the body of the uterus by a long pedicle, and was of the size of a large walnut. Lastly, on the left side of the lower half of the body of the uterus were two more small (intra-mural) tumours. In all there were at least seven tumours—two peri-uterine, or sub-peritoneal, three intra-mural, and two sub-mucous. On section each of these presented almost the same structures, being made up principally of coarse bundles of muscular tissue, with connective tissue. In the cervix uteri there were several mucous polypi containing a glairy fluid.

(The two specimens last described were exhibited during the session 1873-74.²)

Paper:³ In November, 1873, my attention was directed to an extraordinarily small stomach in an aged male subject in the Queen’s College Anatomical Rooms. The whole body was much emaciated, and the heart very small, being considerably smaller than the closed fist of the body.

The intestines were very pale, and only a little more than half the normal size, and the villi in their interior were so much atrophied as to be hardly visible. The liver and other abdominal organs were small, but healthy, and the lungs normal.

The stomach maintained most of its ordinary relations to surrounding parts; but as it lay somewhat more vertically than usual, it was confined almost entirely to

¹ The Diseases of Women, p. 560. 1872.

² [Page 1179.]

³ [Dublin Journal of Medical Science, 1875, v59, p200.]

the left hypochondriac region. After its removal from the body with a portion of the duodenum, it presented the following characters:—In appearance it closely approached its primitive condition of a tube, with a pouch on one side. It could scarcely be said to possess a "fundus," the splenic end projecting little, if at all, to the left of the œsophagus; and the curvatures were but slightly marked, both borders being straighter than usual. The pyloric extremity was much thicker than the rest of the stomach, and for an inch and three-quarters from the pylorus it was of nearly uniform diameter throughout, resembling in form and size a portion of hypertrophied intestinal tube.¹ There was no apparent difference in size between the pyloric end of the stomach and the duodenum. The principal dimensions of the stomach, when slightly stretched, were as follows:—

A B.—Greatest length from most prominent point of splenic end to pylorus, six inches;

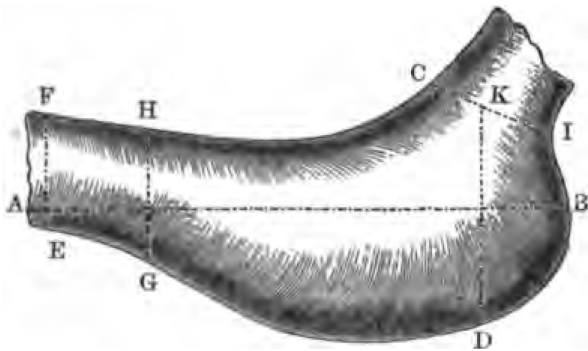

C I.—Diameter of cardiac orifice, one inch and a-half;

K D.—Greatest depth from cardiac orifice to great curvature, two inches and three-quarters;

E F.—Diameter at pylorus, a little more than one inch and a quarter;

G H.—Diameter, one inch and three-quarters to left of pylorus—about one inch and five-eighths.

On making an incision parallel with, and near to

the small curvature, all the coats were found to be thickened to a greater or less extent, more especially at the pyloric extremity, where the section had almost the colour and consistence of fibro-cartilage, and was twice as thick as at the cardiac orifice. The serous coat was of an opaque white colour, and presented no marks of ulceration. The muscular coat was much hypertrophied. The mucous membrane was pale and thick, and thrown into longitudinal rugæ along the great curvature. On the anterior wall, close to the small curvature, and two inches and a-half from the pylorus, was an ulcer of the size and shape of a four-penny piece, which involved only the mucous and submucous coats; its edges were sharp cut and not raised, and the surface

smooth and of a greyish colour.

Microscopical Appearances.—The microscopical examination was made by Dr. T. Cranstoun Charles, in the Brown Institution, London, under the direction of Dr. Klein.

The stomach was left in methylated spirit for several weeks, and a number of pieces were then cut from it at different parts, and hardened in absolute alcohol. These were next embedded in wax, and then vertical sections made in the usual way. After having been stained in hematoxylin solution, and immersed in oil of cloves, the sections were mounted in Canada balsam.¹

All the coats were observed to be more or less hypertrophied, but the greatest increase was in the submucosa. Here the thickening was due to a deposit, or new growth, of an imperfectly fibrillated tissue, resembling connective tissue in an early stage of development. Towards the mucosa the growth consisted entirely of lymphoid corpuscles, which replaced in great part the muscularis mucosa; but towards the muscosa the tissue became fibrillated like imperfectly developed fibrous tissue, the fibrillation being best marked close to the muscular coat.

The mucosa was slightly thickened, and the muscosa more so, but little or no increase could be detected in the fibrous element of the latter, while the lymphatic spaces were observed to be greatly increased in number and in capacity.

The blood-vessels were few in number, and the elastic tissue was nowhere increased in quantity.

History.—For the history of the case I am indebted to the medical practitioner in attendance. I give merely a slight sketch of it, as the symptoms and treatment were in no way peculiar:—

August 27, 1873.—W. M., aged seventy-three, presented himself to-day, suffering from occasional vomiting, pain in the epigastric region, and some eructations, with considerable tenderness on pressure over the epigastrium. No blood observed in the vomited matters. The disease was diagnosed to be ulcer of the stomach. Accordingly, trisnitrate of bismuth and compd. kino powder were prescribed, and a sinapism ordered to the epigastrium. He was to take daily a pint of milk mixed with lime water.

September 8.—As the vomiting had been very frequent, emplastrum lyttæ was applied to the epigastrium, but had to be repeated every other day for eight days before vesication could be produced.

September 19.—Since the blister rose yesterday, the patient commenced to improve; and from this date till October 20 he continued better—indeed, he recovered so far as to be nearly free from pain and vomiting, except on one or two days (October 10), when these symptoms returned.

1514

¹ From this peculiarity in its shape, Professor Macalister, of Dublin, when I showed him the stomach, observed the strong resemblance it had to the stomach of the *myrmecophaga*.

¹ See Dr. Klein's paper in Quar. Jour. of Microscopical Science. Vol. XIII., p. 377.

October 20.—The vomiting, with occasional diarrhoea, again supervened, and continued with a few intermissions till his death. Remedies seemed to have little effect in checking the symptoms, and his body became more and more emaciated until November 7th, when he died from exhaustion.

Remarks.—There can be little doubt the above case is an example of that rare disease which has been variously designated as cirrhosis, plastic linitis (Brinton), fibroid infiltration (H. Jones), and sclerosis (Snellen). In it, as in such cases, “there is evidently an exudation occupying the areolar tissue of the stomach, and gradually undergoing a change, in which its development into a low grade of fibrous tissue (like that of a fibroid tumour) is accompanied by a constant decrease of its bulk and increase of its density. The contraction and hardening thus brought about not only seriously damage the function of an organ to which mobility is essential, but they obstruct its circulation, and probably its innervation also; and they inaugurate grave lesions of its mucous and serous coats.”¹ “While the loss by ulceration of a variable extent of the whole thickness of this (mucous) coat is so frequent and dangerous a result of this kind, as really to constitute what might almost be called a termination or event of the malady.”²

According to this view, then, the ulcer is to be considered a consequence of the cirrhosis, and not the primary disease, as some might be inclined to imagine. Besides, we do not find the stomach so much contracted, and its coats infiltrated for so great an extent, in a case of simple ulcer.

Dr. Habershon relates the particulars of a case in which the stomach was very much contracted (six inches by two), and presented internally an ulcer and a villous growth. He believes the changes in the stomach were produced “by inflammation of the mucous and submucous tissues, leading to very slow ulceration in one part; in another to the development of contractile tissue in the substance of the membrane, and producing contraction of the whole organ.”³ This case bears a close resemblance in many respects to the one I have described above; and I think it might with good reason be regarded as an instance of cirrhosis, though Dr. Habershon does not appear to consider it as such.

Cruveilhier gives a plate⁴ of a small stomach with considerable thickening of its pyloric half, due, in his opinion, to hypertrophy of the fibrous and muscular tissues. Perhaps this case, too, would now be looked upon as an example of cirrhosis. In another plate⁵ he delineates a very much contracted stomach, which was taken from a patient who had died from cholera.

With regard to the difficulty of causing vesication in the case above described, I may add that when exhibiting the stomach before the Ulster Medical Society, in 1874, one of the members remarked that he had on several occasions encountered the same difficulty in producing vesication over a subjacent intensely inflamed organ; and that he was generally unable to do so until the inflammation had somewhat subsided, so as to be a source of less irritation internally than the blister was externally. It has been suggested to me, since then, that the cause of the blister not producing any effect in this case might be ascribed to the fact that the system was at the time in too weak a condition to respond to its irritation.

J. W. Browne M.D. then made some interesting observations on partial dislocation of the head of the radius in children.

John Moore, Chairman
January 13, 1875

Ulster Medical Society. Fifth Meeting January 13, 1875

Present, Dr. Charles Purdon (President) in the chair, also Drs. Stewart, John Moore, McCrea, McKeown, Spedding, Fagan, Core, Whitla, and J. J. Charles.

W. A. McKeown, M.D. introduced an aged patient from whom he removed a tumour which involved the eye, eyelids, and orbit. He believed the tumour was of a cancerous nature, but as it had been kept for some time, it was difficult to form a decisive opinion regarding it.

B. H. Spedding, L.R.C.P. & S. exhibited what he considered a “cancerous bladder” taken from the body of an aged female.

The bladder was very much contracted and its walls greatly thickened, but the urethra, uterus, and vagina were healthy. The kidneys had not been examined.

Some of the members thought that the patient had likely suffered from an affection of the kidneys which caused death, and that the changes in the bladder were in all probability due merely to cystitis.

J. J. Charles, M.D. related the particulars of an interesting case of scrofulous pyelitis, and showed the parts. Two of the members thought the case one of calculus pyelitis in its origin, though no calculi had ever been discovered by the patient.

Joseph Mark, M.D. was proposed as a member by B. H. Spedding L.R.C.P. & S. The motion was seconded by Dr. John McCrea M.D.

John Moore, Chairman
January 27, 1875

Ulster Medical Society. Sixth Meeting January 27, 1875

Present, Dr. John Moore (in the chair), Drs. James

Ulster Medical Society
Session 1874–1875
President Charles Nicholas Delacherois Purdon

Moore, Barnett, McCrea, Stewart, Cuming, Whitla and J. J. Charles.

Joseph Mark, M.D. was elected a member of the Society.

J. McCrea, M.D. read a paper on “Rest of the Lung in Phthisis” which elicited an interesting discussion.

James Moore, M.D. exhibited a leg which he had lately amputated for malignant disease of the upper ends of the fibula and tibia.

Professor Cuming proposed A. Dempsey, M.D. as a member of the Society.

C. D. Purdon, Chairman
February 10, 1875

**Ulster Medical Society. Seventh Meeting
February 10, 1875**

Present, Dr. John Moore (Ex-President) in the chair, Drs. Stewart, Core, C. D. Purdon, Mark, Fagan, and J. J. Charles.

A. Dempsey, M.D. was unanimously elected a member of the Society.

J. Fagan, F.R.C.S.I. introduced a patient on whom he performed amputation of the thigh, and read notes of the case. He also shewed a patient from whom he removed a urethral calculus by incision and made some remarks on the operation.

Some of the members took exception to the reader’s views on the removal of calculi from the urethra and thought incision should always be the “derriere resort” in such cases.

W. Whitla, L.R.C.P. being absent, Mr. Moorhead give a short account for him of a case of rupture of the liver from external violence.

John Moore, Chairman
February 24, 1875

**Ulster Medical Society. Eighth Meeting
July 24, 1875**

Present, Dr. John Moore (Ex-President) in the chair, Drs. Cuming, Dill John W. Browne, Stewart, C. D. Purdon, Dill [sic], McCrea, Whitla, Dempsey, and J. J. Charles.

Professor Cuming, M.D. exhibited a specimen of aneurism of the heart and detailed the history of the case.

The President read a paper on the “Factory Reports of the last two Epidemics of Smallpox, and the means which proved successful in checking its ravages”.

Paper:¹ *The epidemic of 1871 came on so unexpectedly that it found us almost unprepared, and from the long interval that had elapsed since the last attack the public had forgotten the necessary precautions to prevent its progress; consequently, when the parties were attacked, vaccination and isolation were not suffi-*

ciently attended to, and the disease progressed so rapidly amongst the labouring classes that the Poor Law Commissioners issued a circular to the Poor Law Guardians, requesting them to send & copy to all proprietors of mills and factories, asking them to have all their hands examined, to see if any required vaccination.

And, in order to show how necessary this request was, I may state that in those mills in which this recommendation was attended to (I may mention that it was attended to in very few), and where 12,413 hands were employed, 666 were found requiring vaccination; also in those warerooms in which the notice was attended to, and 1,044 hands employed, 136 required vaccination. The medical gentlemen who examined them informed me that numbers presented themselves, saying they had been vaccinated, but, on examining their arms, the cicatrices were found not to be the true ones; and if the inspection had been carried out in the way the Commissioners intended, the results would have been similar to that in the Ligoniel district, which formerly suffered severely. This district has within its boundaries four mills, one print works, one damask manufactory, and two bleach greens, and contains about 5,000 inhabitants. The medical officer vaccinated and re-vaccinated every one that could be induced to allow him to do it; but at the Old Park Print Works the operatives would not submit until the outbreak took place, when they were all vaccinated, and the spread of the disease became checked. During the year preceding he re-vaccinated 495 cases, as well as vaccinated 173 new ones, and the consequence was that in the entire district, except the Old Park Print Works, there were only five cases of small-pox; and you might have drawn a line where his district commenced, and that of the town ended; for on the other side, in a street adjoining, the epidemic was raging. During this time the dispensary officers were actively engaged in vaccinating all that could be persuaded to allow it, but with little apparent benefit, owing to the operatives coming out of hospital while in the infectious stage of the complaint, and trying to get into their work again, and in some cases too successfully. At this time, when the complaint had caused a complete panic amongst the workers, Mr. Baker—himself a medical man—seeing that the directions issued by the Poor Law Commissioners were unsuccessful in checking the progress of the disease, and knowing that the mills and factories were too often hot-beds of the disease, made such representations to the Secretary of State that he was instructed to call into action the services of the certifying surgeons, in order to check the progress of the epidemic. Accordingly, he drew up the following circular:—

“Factory Inspectors’ Office.

“Dear Sir,—It appears that many persons employed in factories have never been vaccinated, and that the

¹ [Dublin Journal of Medical Science, 1875, v59, p558.]

Number of Persons employed in Mills, Factories, &c., in Belfast, who were attacked with Small-pox in the Epidemics of 1871 and 1874.			
1871 Number of Hands Employed In Mills, Factories, &c	Number attacked with Small-pox In the Epidemic Of 1871	1874 Number of Hands Employed in Mills, Factories, &c	Number attacked with Small-pox in the Epidemic of 1874
In Spinning Mills and Weaving Factories, In Warerooms,	32,521 1,774	674 34	33,799 1,508
In Tobacco Factories,	264	2	222
In Pork Store (Cutters),	245	None	178
In Felt Works, ¹	150	None	167
Total	44,318	837	45,550
			135 (103 adults, and 32 young persons.) 11 adults. None. None. None. 176, (137 adults, and 39 young persons)

present spread of small-pox is, in some instances, due to this neglect; the Certifying Surgeons, scattered over the country and possessing considerable influence with the people among whom they reside, have peculiar opportunities, incidental to the discharge of their duties, for ascertaining and remedying this evil.

“The Secretary of State, therefore, directs us to suggest to you, whenever any person, under 16 years of age, applying for a certificate, has not been vaccinated, to represent both to the parents and the employers the danger thus incurred. An employer would be showing only due regard for the interests of his workpeople if he made vaccination a condition of employment: for so indifferent are many people to the risk of infection that they may be found working, even though there may be one among them with the eruption out at the time.

“We shall be glad to hear from you the result of your efforts in this matter.

“We are, Sir, yours truly,
“Alexander Redgrave,
“Robert Baker,
H.M. Inspectors of Factories”

This circular was signed by the Inspectors, and sent to each certifying surgeon in the kingdom, who at once followed the instructions, not only in examining each applicant, and causing those that required vaccination to be vaccinated, but also prevented those that were infected from entering the mills, &c. The beneficial effects of these measures were very soon apparent, and in a very short time the epidemic began to decline, and soon passed away. These sanitary precautions continued to be used as directed, and each year about 8,000 young persons were examined; and in the interval that

¹ The number attacked in other employments need not be given here.

elapsed between the two epidemics of 1871 and 1874 upwards of 1,000 young persons were detected who were either unvaccinated or required to be re-vaccinated, on account of being unsuccessfully operated on; and now scarcely a week passes without from two to four persons being detected and required to be re-vaccinated. The consequence is that the disease that has just passed away, in place of being the scourge that it formerly was, only assumed the character of a slight epidemic. I append the statistics of the two epidemics.

Professor Dill, M.D. give an account of a case of hydramnios with an anencephalic fœtus. Exhibited the fœtus which was aged 7 months, and presented a spina bifida and talipes varus of the right foot.

Paper:¹ A Case of Hydramnios, with an Anencephalous Fœtus. By Professor Dill, M.D.

Mrs. K., aged twenty-two, came first under my care in the early part of the year 1874, for simple ulceration of the os uteri, and having received the necessary treatment, she soon recovered.

I discovered from herself that shortly before this she had had a premature confinement, the details of which I am unable to state. I may say, however, she is of opinion that the womb owed its recent condition to the manner in which the fœtus on that occasion was removed.

On the 15th of January, 1875, Mrs. K. again called upon me, to secure my attendance at her confinement, which she expected would take place on or about the 10th of April, and she appeared to be in good health and spirits.

On the 23rd of February I was requested to visit her, which I did at 11 o'clock a.m. I found that labour had set

¹ [Dublin Journal of Medical Science, 1875, v59, p560.]

in, that she had been complaining through the most of the night and all that morning, and that labour was now pretty well advanced.

I ascertained, on making the necessary inquiry and examination, that she had reached the thirty-second or thirty-third week of utero-gestation; that the abdomen had latterly increased in size very rapidly: that it was globular in form, and prominent at a point immediately below the umbilicus; that there was great tenseness of the abdominal parietes, and that the surface did not present the usual irregularities which are recognised in the normal condition of pregnancy. The foetal movements were believed to be absent, but, if present, they were so very feeble as scarcely to be felt, and this condition had existed a fortnight. Mrs. K. had suffered considerably from pain over the abdomen, especially in the left side, between the false ribs and the crest of the ilium.

There was œdema of the lower extremities, and the labia were very large and pain fully distended. On examining the vagina, the lower segment of the uterus was found to be more than usually distended; the os was dilated; the membranes were so tense, strong, and full, as not only to present an obstacle to their descent, but also to render it impossible to discover the present-ing parts within.

Under these circumstances there could be no difficulty in arriving at the diagnosis that we had at least a well-marked case of hydramnios, and this opinion having been formed, there was as little difficulty in determining the appropriate treatment—namely, puncturing the membranes.

This having been done, although vessels supposed to have been sufficiently large were brought into requisition, the quantity of liquor amnii was so great, that after filling the vessels to the amount of over two gallons, I believe fully an equal quantity of the waters escaped over the bed and the floor. The lady was soon heard to express her alarm at the sudden and marked decrease in her size; at the same time she stated she had obtained great relief. The abdomen and uterus were promptly grasped by the nurse, whilst I, in making a vaginal examination, discovered a small foetus lying across the mouth of the womb; the lower extremities were easily seized hold of, brought down, and the foetus extracted in a short time. The placenta followed in a few minutes.

The child (a female) was happily still-born, as there were deficiencies of certain parts. It appeared to have arrived at the seventh month. The case altogether presented some features of importance. The foetus was an interesting variety of monstrosity, being anencephalous.

In this case there was not the total want of the bones at the upper part of the cranium, but the skull ran backwards so abruptly as to leave no forehead, and little space for the encephalon.

There was also existing a spina-bifida, extending from the nape of the neck to the upper lumbar vertebræ. The membrane over it had evidently given way in utero, and the fluid had poured into the amnion. The foetus bore another mark of deformity—namely, talipes varus of the right foot, which is often found to co-exist with evident derangement of the nervous centres, as in acephalous, hemicephalous, and spina-bifida subjects.

Such cases are, fortunately, comparatively rare. In a large and lengthened midwifery practice I have only met with three anencephalous monsters, and the liquor amnii was found to be in excess in all. Many explanations have been offered to account for the anencephalous foetus, but I think such cases go far to confirm what Professor Rudolphi believed to be the true origin, or cause—namely, embryonic hydrocephalus. He has described an embryo, on the upper part of whose head was a vesicle ready to burst; a second, in whom the envelopes of the brain had burst, the pieces floating round the base of the skull; and a third, in whom these floating remnants were partly gone, thus verging on the common acephalous, as we find when born at the full period of gestation.

This opens up another subject for interesting inquiry—namely, the origin of the excessive quantity of the liquor amnii which accompanies the anencephalous foetus, and which may also accompany spina-bifida.

I am of opinion that the excessive quantity of liquor amnii will not be found to exist unless the sac containing the fluid either in the head or spine bursts and pours its contents into the amnion. All the cases and preparations bearing on this point which have come under my notice would accord with this theory.

John Murray, Chairman
March 10, 1875

Ulster Medical Society. Ninth Meeting March 10, 1875

Present, Dr. John Moore (Ex-President) in the chair, also Drs. Stewart, Core, J. W. Browne, Fagan, Dempsey, Whitla and J. J. Charles.

J. J. Charles, M.D. exhibited a recent specimen of “Hydatidiform Mole”.

W. Whitla, L.R.C.P. exhibited an upper extremity which had been removed that day at the shoulder joint by Dr. Murney.

The whole of the soft parts had been lacerated to an extraordinary extent in one of the mills in town.

John Moore, Chairman, March 24, 1875

Ulster Medical Society. Tenth Meeting March 24, 1875

Present, Dr. J. Moore (Ex-President) in the chair, also Drs. Stewart, Fagan, Dill, Whitla, Dempsey, Scott and C. D. Purdon and J. J. Charles.

J. Fagan, F.R.C.S.I. read notes of a case of what he considered acute inflammation and suppuration of the sacro-iliac synchondrosis and introduced the patient.

J. M. J. Scott, M.D. gave the history of a case of encephaloma of the testis and exhibited the gland.

Professor Dill, M.D. read a paper on puerperal convulsions.

C. D. Purdon

**Ulster Medical Society. Eleventh Meeting
April 14, 1875**

Dr. C. D. Purdon (President) in the chair, also Drs. J. W. Browne, Dempsey and J. J. Charles.

Dr. C. D. Purdon gave an account of a case of ovarian neuralgia in which he had found Sal Ammoniac very useful.

J. J. Charles, M.D. exhibited a dissection of the parts in an old dislocation of the elbow.

Paper:¹ In the body of a strong muscular male, aged forty-four, both bones of the left forearm were dislocated backwards. The extremity affected was almost as well nourished as the other. The forearm could not be flexed to an angle less than 100°, but it could be abducted to a right angle. Adduction was much less extensive than abduction—the parts being made more tense in the former movement, but relaxed in the latter. The external condyle was on a lower level than the internal.

The pronator radii teres, in addition to its normal origin from the internal condyloid ridge and internal condyle, was firmly attached, along with the common tendon of the flexor muscles, to the inner prominent edge of the trochlea, but that portion of it which lay between the condyloid ridge and the trochlea was quite pale and atrophied from disease, and very unlike the rest of the muscle. Its second head having taken origin, as usual, from the coronoid process, the muscle ran nearly horizontally to its insertion. The median nerve was much flattened, and the brachial artery somewhat contracted, where they lay over the prominence of the trochlea.

Consequently the radial and ulnar arteries were not so large as in the other extremity. The brachialis anticus had contracted adhesions to the anterior surface of the trochlea and capitellum. The anterior ligament was entirely absent, except below, where it was attached to the ulna and the lower surface of the trochlea and capitellum, but its place was taken above by the brachialis anticus. The triceps was normal; and the anconeus was adherent to the posterior surface of the orbicular ligament, which seemed to form the most important part of its origin. The posterior ligament had the usual connexions, and was made tense by a small degree of flexion. The internal and external lateral ligaments, as well as the orbicular, were almost normal.

The internal condyle of the humerus was very prominent, whilst the external was almost entirely concealed. The coronoid process gave attachment to the usual muscles, but was displaced backwards and slightly outwards, so that its apex projected into the lowest part of the olecranon fossa. One or two small pieces, however, had been broken off the outer portion of this process, and were situated on the outside of the great sigmoid cavity. The large sigmoid cavity was occupied by a small quantity of adipose tissue, and the cartilage lining it was considerably altered. The head of the radius was somewhat enlarged, and retained its ordinary relations and connexions with the ulna, but was dislocated backwards and slightly outwards, so as to articulate with a cavity formed for its reception on the posterior surface of the humerus outside the olecranon fossa. Besides, the head of the radius articulated above with a strong process of new bone, which, being attached to the posterior aspect of the humerus outside the olecranon fossa, took the place of the capitellum and served as a point d'appui for the radius superiorly. There was also a smaller process of new bone on the back of the internal condyle to articulate with the inner part of the coronoid process.

It will be observed, then, that the radius and ulna were displaced farther upwards on the outside than on the inside. The force, therefore, which produced the luxation must have tended to abduct the forearm, and, at the same time, to drive the radius and ulna upwards—hence the obliquity of the lower end of the humerus.

History unknown; but as the man was frequently inebriated, it is believed he received the dislocation in a mêlée. The accident likely occurred from sixteen to twenty years before his death.

Dr. J. W. Browne proposed “That the best thanks of this Society be accorded to our worthy President for the dignified manner in which he has occupied the chair this session, and for his gentlemanly bearing towards every member of the Society”.

Dr. J. J. Charles seconded the resolution, which was passed unanimously.

Dr. Purdon having replied, the meeting separated.

**Ulster Medical Society Special Meeting
July 9th 1875, at 7:30 o'clock**

This meeting was called in accordance with the wish of the Council which met on the 7th inst., “To consider the proposed Pharmacy Bill, and, if necessary, adopt a petition to Parliament regarding it”.

In the absence of the President, Dr. J. W. T. Smith was called to the chair. There were also present Drs. Whitaker, James Moore, Ross, Core, Ball, Fagan, Whitla, Spedding and J. J. Charles and Mr. Pring.

Mr. Pring having explained the different clauses of the Bill, Dr. Whitaker read a Petition to Parliament containing objections to the Bill.

¹ [Dublin Journal of Medical Science, 1875, v60, p74.]

The Petition having been modified at the suggestion of members, Dr. James Moore proposed and J. Fagan F.R.C.S.I. seconded the resolution "That the Petition now read be adopted".

Passed unanimously.

Dr. Ross then moved "That two Petitions be [prepared?] and one forwarded to Lord O'Neill for presentation to House of Lords, and the other to Mr. Corry for the House of Commons: and further that a printed copy be sent to each of the Irish Members".

This resolution was also passed.

Annual Meeting Session 1875-76

Present, Drs. John Moore in the chair, John MacCormac, Whitla, Fagan, Core, Wheeler, Dempsey, Ball, Bolton, Spedding, J. W. Browne.

The minutes of the Annual Meeting of 1874 were read and confirmed.

Dr. J. W. Browne, Secretary *pro tem* read the report of Council. Proposed by Dr. Spedding and seconded by Dr. Fagan that the report of Council be adopted and entered upon minutes.

Dr. Fagan, Hon. Treasurer, then read a statement of accounts.

The following office bearers were then elected.

President T. K. Wheeler M.D.

Vice Presidents G. F. Wales M.D. & Richard Ross M.D.

Council Dr. Spedding, Dr. John Moore, Dr. Core, Dr. Whitla, Dr. Murney J.P., Dr. John MacCormac.

Secretary J. Walton Browne B.A. M.D.

Treasurer John Fagan L.R.C.S.I.

The two following gentlemen were proposed as members of the Society; to be balloted for next week. Dr. B. Coates, House-Surgeon, Royal Hospital, proposed by Dr. John Moore, seconded by Dr. Fagan. Dr. S. Merrick, Resident Superintendent, Belfast Hospital for Insane, proposed by Doctor John Moore and seconded by Dr. Fagan.

The Secretary to communicate with Dr. Torrens regarding his subscription in arrears (two years).

Proposed by Dr. Dempsey and seconded by Dr. John MacCormac that copies of the rules be printed and presented to each member upon joining the Society.

Thomas K. Wheeler

Council Report 1875-76

The Council have much pleasure in submitting ...

ULSTER MEDICAL SOCIETY

SESSION 1875–76

The First Meeting of Ulster Medical Society 17 November 1875

President (Dr. Wheeler) in the chair, Drs. John Moore, Ross, Whitla, Fagan, J. Walton Browne, Core, J. W. T. Smith, Dr. Dempsey, McKeown, Coates.

The members proceeded to ballot for S. B. Coates, House-Surgeon at the Belfast Royal Hospital, and Dr. R. S. Merrick as members of the Society. Both gentlemen were elected unanimously.

Dr. Wheeler (the President) thanked the members of the Society for their kindness in electing him to the chair.

Dr. Fagan L.R.C.S.I. read a paper upon a case of calculus of the urethra and also related the leading symptoms of a second case.

He exhibited the calculi removed; also Durham's urethral forceps.

Dr. J. W. T. Smith related a case in which a calculus was lodged at the neck of bladder and Smith Thompson [sic] pushed it back into the bladder, remarking that it was easier to extract the stone than to push it back.

The President mentioned two cases of calculi which had occurred in his practice.

The President read notes of cases of puerperal convulsions. He brought forward the history of five cases.

All treated without bleeding. He advocated the early evacuation of the contents of the uterus, and free purgation.

Dr. J. W. T. Smith also approved of the treatment recommended by the President. Dr. Smith had not been satisfied with the use of chloroform in convulsions.

Dr. Ross used hydrate of chloral in these cases with good effect. He had no faith in bleeding.

Dr. J. W. Browne stated the causes of convulsions as laid down by Barnes; also some peculiar symptoms noted in case No 5.

Dr. Dempsey mentioned that bleeding is still in vogue at the Coombe Lying-In Hospital.

Dr. McKeown related a case of chronic disease of the kidneys in which bleeding was used.

Dr. Core also declared a case which had occurred in the Union Hospital.

Dr. John Moore has had ten cases of convulsions in his practice. He does not approve of puncture of membranes in the early months of pregnancy.

Dr. Moore has also bled with effect; he would not like to give up using the lancet. He has also used chloral largely and efficiently.

Dr. Whitla brought forward a case of atropine poisoning. Patient had taken $\frac{1}{4}$ grain of atropine. Four and half grains of [asseum?] were given inside five hours.

Thomas K. Wheeler

Second Meeting 1st December 1875

President (Dr. Wheeler) in the chair, Drs. Whitla, J. W. Browne, Coates, Dempsey, John Moore, Wales, Mac-Cormac, Core.

Dr. Whitla read a paper entitled "Uræmia", endeavouring to prove that uræmic "poisoning" may occur also in connection with diseases of the liver.

Paper:¹ *At the last meeting of the Ulster Medical Society we enjoyed the privilege of listening to the President's most interesting and valuable series of cases of puerperal eclampsia. The paper, which was an essentially practical one, was all the more valuable because the author chiefly confined himself to his most successful treatment of this very formidable and too often fatal affection. If I err not, he stated at the beginning of his remarks that it was not his intention to enter into the pathology of the disease. The few remarks in this paper on "uræmia" are merely intended as a preface to one on Puerperal Eclampsia.*

With the symptoms of this poison (uræmia), and its most frequent cause, Bright's disease, it is wholly unnecessary to take up the time of a Society like this, where every one is so thoroughly acquainted with them, and it is merely my intention to show that the different forms of Bright's disease, or desquamative nephritis, are not the sole causes of this affection. Excluding diseases of the chest, there is no class of cases more common in the medical wards of an hospital than diseases of the kidneys; and perhaps next to these would come the various affections of the liver, especially cirrhosis and cancer. During the early part of last year there were in hospital several patients dying from Bright's disease, and at the same time there happened to be an unusual number of structural liver cases in the wards; and I was forcibly struck with the similarity of the symptoms of these two very different and opposite affections.

By closely watching the progress of a few patients in the advanced stage of kidney disease one becomes familiar with nearly all the phases of chronic uræmia, but here a condition presented itself identical in all respects with this, yet arising during the progress of an essentially different disease. At first I was led to believe that in these cases the kidneys were diseased in addition to the liver, but in some instances where I had the opportunity of making post mortem examinations I found these organs healthy and free from any organic change. In May, 1874, Dr. Murchison's Croonian Lectures on the functional affections of the liver were published in the Lancet, and in one of these valuable productions (which I regret being unable to lay hands on at

¹ [Dublin Quarterly Journal of Medical Science, 1876, v61, p107.]

present) he clearly points out a most important function of the liver.

Dr. Murchison, supported by high Continental authority, states that one of the chief duties of the liver is to lay hold of the effete albuminous compounds, the products of wear and waste in the blood, and to reduce these to their most soluble form, urea, in order to present them to the kidney in a condition capable of being easily and rapidly eliminated. According to these authorities, one may say, if I understand them aright, that it is the liver which manufactures the urea, the office of the kidney being merely to throw it out after its elaboration; consequently, when this function of the liver is deranged, these products are not reduced to urea, but the process stops short, and intermediate compounds—tyrosin and leucin—are formed, substances which the kidney cannot so easily eliminate, and which consequently accumulate in the blood and give rise to the same symptoms as urea, from which, in chemical composition and physiological effect, they differ little, and may be practically regarded as modifications of this substance possessing lesser solubility.

When I use the words “uræmic poisoning,” I wish it then to be understood that I refer to two similar conditions produced by two very different causes—in one the diseased kidney refuses to throw out the already manufactured urea, in the other the healthy kidney is unable to excrete the deleterious products of disintegrating albumen less oxidised than urea. The present state of our pathological knowledge does not enable us in all cases to discriminate clinically the causes at work in producing these identical conditions, especially as we have reason to believe that both factors are operating in the majority of cases of uræmia.

Cirrhosis, by destroying the secreting texture of the liver, produces this derangement of its function, and the consequent retention of these substances gives rise to symptoms of uræmic poisoning. The convulsions and other symptoms met with in the rare disease, acute yellow atrophy of the liver, Dr. Murchison looks upon as owing to these poisons; and, if I mistake not, he goes so far as to say that this form of poisoning is not the uncommon wind-up of the long train of symptoms met with in cases of advanced structural disease of the liver. He believes in this way, too, is accounted for also the typhoid condition which characterises many of the profound lesions of the system. An excellent example of this typhoid condition, associated with symptoms of uræmia, presented itself in the case of Mary B., which I had the honour of bringing before the Society in April, 1874. In this case no trace of disease could be detected anywhere; her delirium was considered to be owing to typhoid fever; the patient died after a few days illness, evidently from some mysterious blood poison; and on opening the abdomen four-fifths of the liver was converted into a bag of pus, though not a single symptom pointed to this organ during life.

Of a considerable number of cases of cirrhosis of the liver, and a few of cancer of this organ which I watched in hospital and kept under observation after leaving it, in the majority death from uræmia occurred. Though these facts are very interesting from a pathological point of view, they are not of much practical importance if only occurring in the last stage of a disease, nor of much diagnostic value, since the affection is obvious before their development. But I am satisfied that uræmic poisoning may be the first symptom of structural disease of the liver, and it seems possible that it may arise also from a purely functional affection of this organ; and I hope to lay this before the Society in my next paper as an explanation of the pathology of puerperal eclampsia in those cases characterised by absence of structural kidney disease.

When we know positively that advanced structural disease of the liver nearly constantly ends in uræmic death (provided the patient be not cut off by some complication), and when we, over and over again, find in the bodies of persons dying from other causes livers largely diseased and extensively destroyed, without a single symptom pointing to derangement of this organ during life, it is easy to see of what vast practical importance this cause of uræmia becomes.

Long ago every obscure disease characterised by the presence of coma and convulsions was put down to apoplexy, but in later days, since the researches of Dr. Bright, it seems the fashion to class them as diseases of the kidney; it is not a very rare thing to hear of sudden deaths preceded by coma and convulsions, especially in children, where the post mortem examination reveals no traces or disease in either brain or kidneys; and we find it sometimes noted as a matter of little moment that the liver is found much enlarged.

In my own short experience of nearly two hundred autopsies during the last two years, I can recall but a few cases where this now seems to me the most satisfactory explanation, though at the time I could offer none.

I will refer to my notes of one case. In January, 1874, a man, aged thirty-nine years, was admitted to the Belfast Royal Hospital suffering apparently from bronchial affection. He had been ill about a week. On examining his chest no evidence of disease was detected, though he suffered from considerable dyspnoea, and had a harsh barking cough. His body was evidently well nourished. Owing to the absence of physical signs, acute tuberculosis was suspected, and merely expectant treatment adopted. He remained in the same condition till about the tenth day after admission, when sudden coma set in, with convulsions, from which he recovered under purgatives and the use of the blanket-bath—only, however, to be attacked the next day, when he died, after being nine hours comatose, with frequent convulsions. During life his urine was examined, but with negative results; unfortunately, tyrosin and leucin

were not tested for. Careful examination showed complete absence of either casts or albumen.

Autopsy twelve hours after death.—Lungs healthy; nothing in them to explain the cause of the dyspnœa. Brain healthy. Kidneys—weight, normal; appearance, healthy; consistence, a little firmer than natural—left slightly lobulated. Liver fatty; weight, nearly seven pounds; under the microscope, cells filled with oil.

I could form no idea of the cause of death after examining every organ in the body; it seemed probably renal, till the kidneys were carefully examined under the microscope, but no disease was found in them. This case, read in the light of more recent pathology, is, perhaps, capable of explanation.

Looking at urea or its modifications as toxic poisons, and keeping in mind some of the most important functions of the liver, we are able to afford an explanation of many things very difficult to otherwise understand. Like many other poisons, after a time the system becomes very tolerant of its action, and the nerve centres, accustomed to the gradually-vitiated blood, are in a condition ready, as it were, to rebel at a moment's notice on the least additional increase of poisoned pabulum; when matters are thus evenly poised, suppose any trivial cause interferes with the function of the liver, the last straw is laid on, and the result is—a convulsion. On the other hand, we see patients smitten down and prostrated with this poison, and watch the progress of Death as he comes slowly and steadily on grasping his victim, who succumbs quietly, and passes away without one struggle. Is it not possible that two organs are at fault in the first case, and only one in the latter? Indeed, it may even come to be a disputed question whether the kidney alone, by its disease, is capable of producing death from uræmia.

Shortly after the first dawn of light was shed upon the pathology of kidney diseases, to find albumen and casts in the urine of a patient was to give him a very limited term of existence; now we know these are not incompatible with a lengthened and enjoyable period of life. We put under the microscope two samples of urine from different patients the subjects of this disease; we see in one here and there a few small scattered casts, and these, too, found with difficulty; yet this patient may have but a few weeks to live, while in the other we find the field studded over with casts of such magnitude as to prove they are the models of tubes devoid of all epithelial or excreting tissue, and full of oil and fat cells, evidently from a gland whose structure is apparently almost destroyed; nevertheless, its owner may live and enjoy life for a good long time till perhaps cut off by some unexpected complication; we have no more reason to wonder at this than at the case of a patient who dies from a slight contraction of the mitral valve, while his neighbour lives with his mitral no longer a valve but a mere slit, till old age carries him home. Yet these admit of an explanation if we knew it; and is it

not possible that the life of a diseased kidney is depending upon its liver? If so, a very material point is gained in prognosis and treatment. A word about the uræmia of scarlatina. My experience is far too limited to generalise, but perhaps I shall be borne out in stating that convulsions occur more frequently in this form of desquamative nephritis than in the acute affection, the result of exposure and other causes. Dr. Samuel Fenwick and others have found in the stomach tubes and the Lieberkühnian follicles of the intestines in the bodies of patients killed by scarlatina, changes which prove that a process takes place in the epithelial lining of these glands analogous to the desquamation occurring on the surface of the body, while a very eminent authority affirms that this is the true pathological explanation of the lesion of the kidneys which, he says, is caused by the shedding of the epithelium lining in scarlatina, the convoluted tubes of these organs. But I can go one step further, as I hope, from changes which I have noticed in scarlatinal blood, to demonstrate under the microscope, before the conclusion of this session, that the epithelial lining of the blood vessels of the body suffers the same destruction as the cuticle, and that partially broken-up cells and nuclei corresponding to the pavement on the fenestrated coat of Henle are sometimes to be found in the circulating fluid during the early desquamative stage of scarlatina.

Many things go to show that at this stage of the disease the blood is charged to excess with excrementitious matters, consequently great extra work is required of the liver to elaborate urea from these, which work the liver does, though more quickly and less perfectly than it should, and the resulting modifications or substitutes for urea cannot be thrown out sufficiently rapidly by the kidneys, already overtaxed and unhealthy, and uræmia results. If, then, this state of matters exists, we see what a very important part the liver plays in the uræmia of scarlatina.

The hypothesis of a condition somewhat like this will go far to explain many cases of puerperal eclampsia characterised by the absence of structural kidney affection. Supported by the researches of Murchison and others, whose labours have thrown considerable light upon the functions of the liver, one may venture to hope, as these functions are better understood and more generally known, that many of the pathological difficulties surrounding diseases of the kidneys will be cleared away. That cases of disease in these organs are turning up now and then which baffle every scientific explanation the practice of most men will confirm; and it is not unlawful, having tried in vain to elucidate them by the light of all that is now known of renal pathology, to turn to the investigation of the conditions of other organs and there seek for hidden associations which may assist us. It was my intention to read the notes of a few cases of this kind which have given me some trouble, but I have already trespassed too much

upon my reader's time, and will conclude by briefly referring to one.

Nearly three years ago a physician in the country sent me a specimen of urine from a patient who had slight anasarca, and requested me to make a careful examination of it. Its specific gravity was 1012. On the addition of nitric acid it was found to contain nearly half the depth of the test tube of albumen; but, notwithstanding the most careful investigation, no traces of casts could be detected; his urine continued highly albuminous for some months, when I saw him and found him a man of fifty-five years of age, in excellent health and spirits, and capable of his usual amount of work—in fact, quite as well as he had been for years, excepting a trouble which I shall mention presently. There was no anasarca, heart, or liver affection. A sample of his urine has been sent me nearly every month since then—sometimes more frequently; it has always been highly albuminous, oftentimes alarmingly so; much time has been spent in examining it microscopically, but only once were anything like casts found in it; it has been examined repeatedly by other microscopists with the same result.

This case seemed worth recording owing to the remarkable absence of microscopic evidence of structural disease; the urine of a healthy patient examined so often and searchingly as his would hardly fail to show some well-formed casts occasionally. Last Christmas morning I received a sample of his urine, which contained one-third albumen; next day I received a letter stating he had been out shooting, exposed to frost and snow. Crystals of tyrosin have been found occasionally, and once little masses of leucin, in his urine, and, strange, the only trouble he ever experiences is owing to violent and excruciating attacks of hepatic colic, which reduce him very low indeed for days. Last time I examined him the extent of hepatic dulness in the mammary, axillary, and scapular lines was normal, and neither atrophy nor enlargement of the liver could be detected.

The supposition of a waxy kidney will not satisfactorily account for this state of matters, the only evidence of disease of this organ being found in the quantity of albumen passed daily; and it is worth while remembering the fact that if a healthy man fasts for twenty-four hours and then eats a quantity of highly albuminous food, such as eggs, large quantities of albumen appear in his urine; as the liver, having too much work to do, permits some of this substance to pass through in a condition unfit for supplying the wants of the blood. When blood so charged with this crude albumen reaches the kidneys it is at once purified by these excretories.

Is it going too far to suppose that some structural or functional derangement of the liver might convert this transient occurrence into a permanent symptom? If not, albuminuria with uræmia might be accounted for

in many cases of puerperal eclampsia where careful microscopic examination reveals no casts.

But in a subject like this there is such scope for theorising that it is well to keep in mind the danger of passing through the region of the probable into the domain of impossibility. We arrive at much more accurate conclusions about the function of the liver from closely and narrowly watching the symptoms in cases where this organ is very extensively diseased than by any series of experiments on the lower animals, where many unfavourable conditions are necessarily induced, and the physiologist will soon learn that from clinical medicine alone must he seek for further light upon this subject. The facts stated upon the high authority of Dr. Murchison and others show beyond doubt that the liver is intimately associated with the elaboration of urea; and if these few remarks ever lead anyone to turn to the liver for an explanation of the many obscure cases of uræmia, its object will be more than fulfilled.

About the diagnosis of uræmia from brain disease, apoplexy, alcoholic poisoning, &c., considerable difficulty is sometimes met with, especially in those cases where a sudden attack is experienced for the first time, and where no history of any renal trouble can be found. In such cases great assistance will be had from careful examination of the condition of the heart, as nearly always distinctive modifications of the heart sounds will be heard, as reduplication of one or both, intensity of second sound, &c., differences also in the arterial tension and cardiac impulse.

Of these none seem so constant or remarkable as muffling of the first sound. In a very interesting case of uræmia, which I saw with Dr. Bell, at Bangor, in June, 1875, in a lady aged forty-six years, the first sound was entirely absent for four days after the cessation of the convulsions, returning suddenly after a strong purgative; it seemed as if due to the resistance offered by the swollen artery to the entrance of blood during the contraction of the left ventricle, so that no wave of sufficient strength to beat against the wall of the artery occurred.

Dr. J. W. Browne read for Dr. Coates (who was suffering from indisposition) a paper upon a case of vesical calculus.

Thomas K. Wheeler

Third Meeting 15th December 1875

Present, the President (Dr. Wheeler) in the chair, Dr. Fagan, Dr. Dempsey, Drs. John Moore and J. W. Browne.

Dr. Fagan read notes of a case of excision of the elbow joint and exhibited the recent parts.

Dr. John Moore read a paper entitled "Prisons and Prisoners" detailing some very interesting matters regarding the County Antrim jail.

Ulster Medical Society
Session 1875–1876
President Thomas Kennedy Wheeler

Dr. Wheeler proposed and Dr. Fagan seconded Dr. Robert Esler as a member of the Society.

Coates, Whitla.

Thomas K. Wheeler, M.D.

Fourth meeting 5th January 1876

The President (Dr. Wheeler) in the chair, Drs. Core, Coates, Whitla, J. W. Browne, John Moore. Several students were present.

Dr. Esler was elected unanimously a member of the Society.

Dr. Coates read for Dr. Murney a case of vesical calculus. Paper amongst the transactions.

Dr. J. Walton Browne read a paper upon a case of cysticercus cellulosæ.

Dr. Coates exhibited a cystic tumour of the kidney.

Thomas K. Wheeler.

19th January 1876

The President (Dr. Wheeler) in the chair, Drs. John Moore, J. W. Browne, Coates, Esler, Dr. Dempsey, Dr. J. W. T. Smith, Dr. Spedding. Several students were present.

Dr. John Moore described a case of spina bifida which was treated by the introduction of the aspirator. Death ensued one week after the evacuation of the fluid.

Dr. J. W. Browne read notes of a case of partial dislocation of the head of the radius.

Dr. J. W. T. Smith exhibited the lungs of a man who had died owing to an attack of double pleuritis.

Dr. Browne exhibited Stokes' instrument for the treatment of granular lids.

Thomas K. Wheeler

Sixth Meeting 2nd February 1876

President (Dr. Wheeler) in the chair, Drs. John Moore, J. W. Browne, Esler, Whitla, Aickin, Dempsey, Spedding, Fagan.

Dr. John Moore related an interesting case of complete paralysis of the body, probably the result of myelitis of the cord.

Dr. Spedding related the history of two cases of intestinal obstruction.

Dr. Walton Browne exhibited Field's artificial membrana tympani.

Thomas K. Wheeler

Seventh Meeting 16th February 1876

Present, (Dr. Wheeler in the chair), Drs. Dempsey, Fagan, Core, Spedding, Coates, J. W. Browne, Aickin, John Moore, Dr. D. Johnson, Dr. Dempsey [sic]. Several students were present.

Dr. Aickin read a paper upon intestinal obstruction advocating the use of a hydrostatic pressure enema placing the head and shoulders downwards, allowing the fluid by gravitation to find its way along the colon.

Dr. Coates read notes of two cases of fracture of the cervical vertebræ.

Thomas K. Wheeler

Eighth Meeting 1st March 1876

Present, (Dr. Wheeler in the chair), Drs. Fagan, J. W. Browne, Coates, Dempsey, Esler, McConnell, Dr. D. Johnston.

Dr. Fagan read a paper upon amputation of the thigh in which he applied torsion to the femoral and dressed the wound with carbolized [tar?] and catgut sutures. The wound healing almost by the first intention.

Dr. J. Walton Browne read a paper upon a case of uterine hæmorrhage.

Thomas K. Wheeler

Ninth Meeting 5th April 1876

Present, Dr. Wheeler (in the chair), Drs. Esler, Whitla, John Moore, J. W. Browne. Several students were present.

Dr. John Moore read notes of a case of tetanus and introduced [the patient] who had been successfully treated by chloral.

Dr. John Moore exhibited a patient upon whom he had performed Syme's amputation at the ankle joint.

Tenth Meeting 12 April 1876

Drs. Wheeler (in the chair), Coates, J. Walton Browne, Fagan, Ross, Dempsey. Several students were present.

Dr. Fagan read notes of a case of excision of the knee joint and exhibited a number of photographs of the parts he had operated upon.

Eleventh Meeting

Present, (Dr. Wheeler) in the chair, Drs. Ross, J. W. Browne, Whitla, McCrea, Coates, John Moore, Fagan, Spedding.

Dr. Fagan exhibited two patients upon whom he had performed excision of the knee joint, the cases were very favourable. Dr. Fagan will bring them under the notice of the Society at some future period.

Dr. J. W. Browne proposed a vote of thanks to the President and Dr. McCrea seconded it. Dr. Wheeler returned thanks.

The President proposed a vote of thanks to Dr. J. W. Browne and Dr. Whitla seconded the vote of thanks.

Annual Meeting held in the Library of the Hospital on Friday Evening November 3 1876.

Present, Drs. Wheeler (President), Fagan, Spedding, J. Moore, Beck junr, Esler, Coates & Whitla.

Dr. Fagan (Treasurer) read his report and explained that owing to some fourteen members not having paid their subscription, he did not balance his books but hoped that next month he would be in a

position to wind up his accounts and report to the Society the result. His report was considered satisfactory and adopted.

Secretary's report and Council report: Dr. Fagan explained and apologized for Dr. Browne's absence. Dr. Browne had asked him to state to the Society that the Council not having requested him to prepare a report, he had not done so. No report then being read it was agreed to ask Dr. Browne to prepare one for next meeting.

Office Bearers: Richard Ross M.D. was appointed unanimously to act as **President**. Dr. Wales and Dr. J. W. Browne as **Vice-Presidents**. Dr. Fagan to continue as **Treasurer**. W. Whitla to act as **Secretary**.

Council. Drs. Spedding, John Moore, F. Beck, S. B. Coates, H. Murney and W. S. Core.

The President introduced the question of the time of meetings and whether this should be monthly or fortnightly. After some general discussion it was unanimously agreed to have the meetings (when possible) every fortnight, and the evenings to be Tuesdays at 8 during the winter, and monthly during the summer (till July 20).

Dr. Spedding proposed that arrangements should be at once made about the Annual Dinner which should be held before Xmas. This was agreed to and a dinner committee of the following gentlemen appointed: Drs. Murney, Fagan, Moore, Spedding and Whitla.

Proposed by Dr. Fagan "That in case the proposed change takes place (in dispensing with a messenger) a suitable Librarian should be appointed, salary to be fixed by the Library Committee. Seconded by Dr. Moore and carried unanimously.

Proposed by Dr. Wheeler seconded by Dr. Spedding that following gentlemen act as Library Committee: Drs. Murney, Moore, Fagan, Coates and Whitla.

After a discussion about the advisability of dispensing with the services of the messenger it was agreed that nothing could be done as the matter was omitted to be put in the circular of the meeting and Dr. Fagan gave notice that he would move the question next meeting.

ULSTER MEDICAL SOCIETY

SESSION 1876–77

First Meeting

The 1st ordinary meeting of the Society was held in the Belfast Royal Hospital on Tuesday evening November 14th 1876.

Present, Drs. Ross (President), Wheeler, James Moore, John Moore, Merrick, Core, F. E. Beck, Beck, Snr., Mr. Grattan, Dr. Gribbin, Esler, Coates, Dempsey, Spedding, J. W. Browne, Whitla.

On the motion of Dr. Browne Dr. Wheeler (in Dr. Ross' absence) took the chair. Dr. Ross entering the meeting Dr. James Moore moved in an elegant and complimentary speech a vote of thanks to Dr. Wheeler for his valuable services during the past session as President. This was seconded by Dr. John Moore and passed with acclamation.

On the motion of Dr. Browne the President, Dr. Ross, took the chair and thanking the Society for the honour of representing them, delivered in an eloquent address the opening lecture of the session.

Paper:¹ Gentlemen,—My first duty, in taking this chair as President of the Ulster Medical Society, is to return you my cordial thanks for the honour you have conferred upon me in electing me to the office. I can unaffectedly say that I would have preferred that your choice had fallen upon some one else who had higher claims than I have. Indeed, I at first hesitated to accept the position, but on hearing that my appointment was desired by a number of my professional brethren, I felt that I would be wanting in a due appreciation of their kindness if I refused so flattering a compliment. I will take this opportunity of making a few observations upon the value of such an institution as the Medical Society, if worked properly. Our worthy ex-President, Dr. Wheeler, notwithstanding the demands upon his time, has shown us a good example in his regular attendance at, and in the interest he has taken in, the meetings during the past Session.

The friction of mind with mind, as iron upon iron, sharpens our faculties and promotes our professional improvement. No one can attend our meetings—listen to clinical facts accurately recorded—see disease or the effects of medical or surgical treatment in the living man—examine morbid specimens in which are exhibited the destructive effects of injury or pathological processes—keep himself informed in medical literature by our circulating library—and fail to find his mind more enlightened and his feeling of self-confidence increased when he holds the scales of life and death in his hands. Knowledge in our profession, as in every

other department of human activity, is endless, and, no matter how great our information, we shall always have much to learn. Some one has written, "In earth there is nothing great but man; in man there is nothing great but mind and we, to whose care is committed this wonderful microcosm, may well magnify our office, but it all the more becomes us to develop, by every means within our reach, our intelligence, skill, and proficiency. The course of nature is doubtless unalterable; but the Almighty has conferred mind on man enabling him to be an interpreter of nature, and by his knowledge of natural laws capable of modifying one law by another. Bacon said that "man commands nature by obeying nature." Nature makes water flow down, but man makes it flow up a hill to fill a reservoir, by modifying, not interrupting, the laws of nature. Likewise in scientific medicine, if we get clear ideas of nature's laws in man and in his environment—or, to go more into detail, if we study man mentally and physically, in health and in disease, acquaint ourselves with his surroundings, the air he breathes, his food, his drink, the accidents to which he is exposed, what is favourable and what is unfavourable to his health—abundant opportunities will be afforded us of bringing to pass results which, but for man's intervention, unaided nature would not bring to pass.

One word upon another advantage of our Association, and I have done. It is as true of individuals as it is of nations, that with the increase of relations and mutual knowledge suspicions and enmities decrease. Our meetings here for the advancement of medicine and surgery, our discussions, and each of us making it our motto, "Gladly would he learn and gladly teach," must tend to the promotion of kindly feelings and goodwill in the members of the Society:—

Friendship is no plant of hasty growth,
Though planted in esteem's deep-fix'd soil:
The gradual culture of kind intercourse
Must bring it to perfection.

Dr. Browne read the Council report of last session which was unavoidably omitted at the Annual Meeting.

It was unanimously adopted.

Dr. Coates read notes of cases of acute rheumatism treated by salicylic acid with remarks on the acid etc.

Paper:¹ Case I.—James Drain, a healthy man, aged about eighteen years, a ticket-collector on a railway, admitted Thursday, 21st September, 1876; had been ill and totally unable to work for six days previous to his admission.

On admission, his hip, knee, ankle, elbow, and right wrist-joints were affected, tender and swollen, the slightest motion causing extreme pain; tongue furred;

¹ [Dublin Journal of Medical Science, 1877, v63, p97.]

¹ [Dublin Journal of Medical Science, 1877, v63, p98.]

copious acid perspirations; had a mitral murmur, which, however, we have reason to believe, existed previously.

At 12 noon, on 21st September (day of admission), his temperature was 102.9° (almost 103°); pulse 83 (normal pulse 55). He was ordered salicylic acid, grs. xv. every hour; this was continued, with but one intermission of an hour, for 14 hours, when the temperature had fallen to 99°; pulse 75. When he had taken the tenth dose the pains had almost disappeared, and at the twelfth dose he could move the limbs freely. On the evening of the 22nd September (day after admission) he had a slight return of the pains, which, however, disappeared at once on the administration of a few doses of the acid. On September 26th he was ordered quiniæ sulph. grs. ½ three times a day, and he left hospital on 3rd October quite well.

Case II.—Lizzie Gamble, a healthy woman, aged thirty, a domestic servant, admitted on 12th August, 1876. She was able to trace her present illness to a severe wetting received about two weeks previous to her admittance.

On admission she was suffering intense pain—knee, ankle, shoulder, and elbow-joints were affected; perspiring freely; tongue furred; bowels constipated; no heart affection. She was put under treatment at 10 30 p.m. on 12th August, and the joints having been bound up with cotton wadding, she was ordered grs. xv. salicylic acid, to be repeated each hour for six hours. At 10 30 p.m. the temperature was 100.8°; pulse 98; and at 3 30 a.m. on the next day, at which time the sixth dose of the acid was given (five hours from its commencement), the temperature was 98.4°; pulse 92. After she had taken two or three doses of the medicine the pains began to disappear, and at the sixth dose she was able to move all the joints freely. She convalesced satisfactorily, getting a few doses of the acid at more remote intervals, then sulphate of quinine for a few days, and left hospital well on 2nd September.

Case III.—Sarah J. Thompson, a healthy woman, domestic servant, aged twenty-three, admitted 15th September, 1876; had been five days ill and confined to bed previous to her admission.

On admission, knees, ankle, shoulder, elbow, and wrist-joints were affected, the pain being of so excruciating a character that she was incapable of the least motion—all the symptoms of acute rheumatism being exceedingly well marked in her case. The joints were enveloped in cotton wool, and at 9 p.m. she was put under treatment, being ordered grs. xv. salicylic acid every hour till eight doses had been given. When the treatment was commenced, Sept. 15, 9 p.m., temperature 103°; pulse 110. Sept. 16, 9 a.m., temperature 100°; pulse 105. Sept. 16, 9 p.m., temperature 99°; pulse 96. When she had taken three doses the pains began to disappear, and when she had taken eight doses were almost gone.

An incident in this patient's case illustrates very well "the rapidity with which the salicylic acid acts"—viz., at 9 p.m. on the 15th Sept. she was unable to make the slightest movement, and at 6 a.m. on the 16th, nine hours after, she, in the temporary absence of the nurse from the ward, got out of bed and walked across the floor—just as she expressed it—"to see what she could do."

She had a slight relapse on the 18th, which was easily cured by a few 10-grain doses of the acid. She convalesced satisfactorily, and left hospital on 7th October.

I will now take the liberty of reading a few general remarks on salicylic acid, its doses, mode of administration, &c.

It is obtained from willow bark, and is only slightly soluble in water, but is soluble in rectified spirit, and in solutions of alkaline carbonates, forming in the latter case salicylates. Indeed, it is used most extensively in the form of the salicylate of soda by Dr. Frerichs, of Berlin, Professor Gairdner, of Glasgow, &c. When pure, salicylic acid consists of shining white needle-shaped crystals, which have a very slight smell—indeed, when perfectly pure, no smell. The advantage of the pure acid is that it can be given internally in considerable doses without any of those unpleasant results which have followed the use of the ordinary commercial acid.

As to the dose in the above cases, the quantity usually given was 15 grains every hour for 8 and in one case for 14 hours. In cases of typhoid fever, Professor Frerichs gives 5.0 grammes (77 grains) in a single dose, each day at 12 noon, with a view to counteract the usual evening rise, with the result of reducing it in 80 per cent, of the cases. Very large quantities have been taken without any deleterious effect. In one case, that of a patient of Dr. Stricker, of Berlin, 22 grammes (340 grains) were taken in 12 hours.

Large doses in some patients produce symptoms allied to cinchonism—viz., buzzing in the ears, and even temporary deafness. The latter occurred to a slight extent in two of the cases treated here. However, the symptoms disappeared very soon after the discontinuance of the medicine.

It may be ordered as a powder; here it has almost exclusively been used, prescribed with a little tinct. of orange and water, giving particular directions as to the bottle being carefully shaken before each dose is measured out. I think it is a matter of importance that it should be given in a proper state of dilution, and have found that when three or four ounces of water were given with each dose the danger of nausea was reduced to a minimum—indeed, in none of the above cases did it give any trouble. Milk should not be given, either immediately before or immediately after any of the doses of the acid, as it seems particularly to disagree.

It seems to make little difference whether the pure acid be given or one of its alkaline combinations, as the

salicylate of soda; the latter has not, however, been tried here. Salicin has been used very extensively by Dr. T. Maclagan, of Dundee, who speaks of it in the highest possible terms. He says of it that "the relief of pain is always one of the earliest effects produced;" that "in acute cases relief of pain and fall of temperature generally occur simultaneously;" that "in subacute cases the pain is sometimes decidedly relieved before the temperature begins to fall;" that "the more acute the case the more marked the benefit produced," &c. I believe these observations are equally true of salicylic acid. Dr. Maclagan gives in an average case grs. xv. to grs. xx. of salicin every hour. As to the effect of either of these drugs on cardiac complication, so frequent in acute rheumatism, I think it can hardly be denied that medicines which cut short the disease, as I think there can be no doubt they do, must render the liability to these complications much less.

In conclusion, I may state that in a very few cases the administration of these medicines has been alleged to have produced rather alarming symptoms. In all probability, in these cases the symptoms were due, not to the acid, but to its being impure. It is a well-known fact that the impure acid contains carbolic acid; also that in poisoning by carbolic acid the urine has a characteristic olive-green colour; that there is stertorous breathing, a burning sensation in the mouth, fauces, and stomach, followed by vertigo, and a feeling of intoxication, great lowering of temperature, and feeble pulse. Now, in the cases which have been reported "of symptoms of poisoning produced by salicylic acid," and markedly so in the cases recorded in this week's *Lancet* by Dr. Tuckwell, of Radcliffe Infirmary, Oxford, the above are almost the exact symptoms which he ascribes to the use of the salicylic acid, but which, I think, we have ample proof to show are due to its impurities, particularly the carbolic acid.

Dr. Core had tried the acid in two cases both of which were very satisfactory. He gave in 6 doses in one case 120 grains and from what he saw and read believed it was the best remedy for the disease.

Dr. Esler tried the acid in one case and was satisfied with its result which was most marked.

Dr. Spedding used the acid in one case only where he could narrowly watch its effects. Though he had given it in several dispensary cases he could not answer for its action. He found in the case referred to that the acid produced in 10 grain doses every hour very alarming apoplectic symptoms. He was satisfied thoroughly as to the purity of the article and he attributed the symptoms to the toxicological effects of the acid.

Dr. Beck, Snr., had very large experience in the treatment of acute rheumatism and he at various periods believed he had found the "true remedy" but after a time he became convinced he must resign

each for another until now he could hardly say which was the most favourable. On the whole he leaned to the alkaline treatment.

Dr. Merrick felt from the pathology of the disease that the alkaline treatment was the safest.

Dr. John Moore thought the treatment of the disease was anything but satisfactory. Contrasted the vagueness of medical theories with the definite results of surgery.

Dr. J. W. Browne was not satisfied with the efficiency of the acid in acute rheumatism. He referred to the cases treated in Charing Cross Hospital and did not believe it had any effect in reducing the temperature.

Dr. Wheeler who highly approved of the alkaline treatment did not agree with Dr. Moore and others who advocated the expectant treatment. He believed much could be done in acute rheumatism. The relief of pain by opium as experienced in his own case was very satisfactory.

Dr. Whitla (Honorary Secretary) thought that before the efficacy of a remedy could be thoroughly established the nature of the disease must be carefully studied.

Acute rheumatism was a disease which in many instances was observed to abort and he believed in a large percentage of cases it did "cut itself short". This explains the history of the treatment; lots of remedies have been warmly advocated as specifics mainly owing to this peculiarity. He believed no conclusion could be safely arrived at till a large mass of evidence was collected.

Dr. Gribbin had used various remedies with varying success; the alkalis were in his hands most successful. He agreed that many cases of acute rheumatism did abort without any remedy.

Dr. Ross (President) in thanking Dr. Coates for his paper said he had appealed to the thermometer and pulse undeniable indications in the treatment of the cases.

He had himself, he believed, introduced the acid into the hospital and was satisfied with its results but he did not believe the best effects would be produced by such large doses. He found most benefit from 10 grain doses every 3 hours.

The motion of the Treasurer was then very freely entered into and after a very general discussion it was agreed to allow the distribution of the journals to go on as before and all the new journals remaining on the table of the Hospital for 1 week before going out.

Members proposed: Dr. Strahan (by Dr. Spedding and Browne) and Dr. Pirrie (by Dr. Esler and Dr. Wheeler).

It was decided that the Annual Dinner would come off on Wednesday 8th December at 6

Richard Ross
November 28th 1876

Session 1876 & 77

Second Meeting 28th November

Present, Doctors Ross, John Moore, Fagan, F. Beck, Browne, Esler, Gribbin, Coates, Pirrie, McKee, Dempsey and Whitla. (12)

A ballot was taken for each of the following gentlemen and they were elected members of the society: Doctors Strahan, G. Pirrie, O'Malley, Graham.

The Treasurer made a statement explaining the condition of the funds of the Society.

The Secretary was directed to communicate with Doctors Murray and Hayes and inform them of the rule bearing upon the subscriptions of the members.

Dr. Beck read notes of a case of tertiary syphilis and exhibited a piece of bone expectorated by the patient.

Paper:¹ Mr. W. came under my care some nine years ago. He was suffering from a chancre, which turned out to be of the true Hunterian character. It left for over three months after it healed the little hard button-like base so characteristic of these sores. He was treated with five-grain doses of the compound subchloride of mercury pill three times daily. The sore was dressed with a mild ointment, composed of the red oxide of mercury.

To all appearances the case did well; the sore healed up without any bubo being produced; the induration likewise disappeared. Some twelve months afterwards he called upon me; he was now suffering from well-marked secondary symptoms in the form of a sore throat, spots on his legs, &c. I put him on five-grain doses, afterwards increased to eight grains daily, of pil. hydrarg. He was also ordered a mixture containing iodide of potash, iron, and a bitter infusion. Under this treatment he made a rapid recovery. I made him continue the medicine for over five months more or less continuously, until every trace of the syphilis had disappeared.

For a number of years he kept quite well, when he again, for the third time, came under my care. This time he was suffering from a well-marked tertiary spot upon his forehead up among the hair; severe pains about his head, neck, and shoulder; his throat also was sore, and his general appearance was very bad. I ordered him a mixture of iodide of potash, ammon. cit. of iron, and infusion of gentian; told him to take extra nourishing diet, and keep himself warmly clad. In spite of all my efforts, the spot on the forehead enlarged, sloughed, and only healed after I removed a piece of necrosed bone about the size of a half-crown; the piece consisted of the outer portion of the frontal bone. In trying to heal the sore I had some difficulty; what eventually closed it up was lint soaked in a saturated solution of chlorate of potash, with oiled silk over. After this little operation he came round rapidly. Some two years

passed, when he appeared again, for the fourth time, three months ago. This time he complained bitterly of his throat—nothing else. It was impossible to see down the throat, owing to his having a creak or stiffness in his neck; head, neck, and shoulders seemed as if made of one piece. I tried every means that I could think of. When I tried to bend back the head, he bent his whole body backwards, and the pain was very severe; his breath was very offensive. I came to the conclusion that he was suffering from severe ulceration, complicated with some destruction of bone. He was again ordered the iodide of potash and iron mixture—his throat to be well sprayed with Condy's fluid. He reported himself worse and worse for a period of six weeks. I was getting uneasy about what would be the ultimate result of the case. Blood and mucus were coming up very frequently, and the pain was becoming intolerable, when suddenly one night he wakened up, choking, and coughing up mouthfuls of blood. When trying to cough up the blood and get breath, a lump of something came away, all covered with a clot. His wife and he examined it, washed it, stuck their nails into it, and came to the wise conclusion that it was bone, and so it was. On minute examination it proved to be the whole anterior portion of the body of the axis. Since this happened he has gone on well, and is, as far as I or he can know, quite recovered, and at his business. I should add that several pieces of mucous membrane were expelled a few days after the bone came away.

I think this case is peculiar from the fact of the tertiary symptoms being so well-marked and so severe, although he was treated secundum artem both for primary and secondary. He was, in the first instance, kept on mercury until the total disappearance of the induration—I always make it a point to do this—and in the next stage, or secondary, he was kept well under treatment until all symptoms had cleared off. That he really was free from syphilis was more or less proved by the fact of his wife having had several children subsequently all healthy, and nursed by herself; moreover, she herself never showed any symptoms of the disease. Lastly, it seems strange how such a portion of bone could come away, and yet the patient make such a good recovery.

The majority of the members present considered the specimen to be part of an upper cervical vertebra.

Dr. Gribbin, speaking on the treatment of syphilis, said after a long experience he never treated a case of syphilis without opium. He believed, from numerous cases brought before him, that the absence of this drug caused eventually tertiary symptoms to arise, and that in a very large percentage of cases of tertiary syphilis, on inquiry he found there had been no opium used. He ventured, he said, no explanation, but had so often remarked this he thought it right to mention it.

Dr. Fagan considered the specimen to be the altered body of the axis. He thought that, as regarded the off-

¹ [Dublin Journal of Medical Science, 1877, v63, p189.]

spring, the period most favourable for transmission was about the time the primary sore healed.

Dr. J. Moore referred to the exanthematous theory of syphilis, mentioning the debt the profession owed to Jonathan Hutchinson for his labours in this field. He related some cases of congenital syphilis which came under his notice in the County Prison, and which seemed to get well without any treatment after running the course of an ordinary feverish attack.

The President (Dr. Ross), in thanking Dr. Beck for his paper, agreed with the remarks made, but considered that, from what they knew at present of the nature of syphilis, it would not be justifiable to allow the congenital affection to run its course without treatment.

Dr. Beck replied to the remarks made.

Dr. Browne (J. W.) read notes of a case of tapping where the bladder was opened in the parieties above the pubes and per rectum. He exhibited the patient who was in a state of convalescence. The wound was completely healed. There was some matter coming from the umbilicus the cause of which Dr. Browne explained was an abscess under the pectoral muscle which travel downwards.

Paper:¹ Joseph Bryant, aged forty-three, a foundry labourer, residing at Coar's-lane, Belfast, was admitted into the Belfast Royal Hospital, under my care, upon the morning of the 27th May, 1876, suffering from retention of urine. He gave the following history:—He had been a hard liver all his life. Twenty-three years ago he had an attack of gonorrhœa, the acute symptoms in a short time yielding to treatment, but followed by a gleet, from which he has suffered up to the present date. For the cure of the gleetish discharge he has used various injections recommended by sympathising friends.

Six years since he noticed the stream of urine becoming small, and slightly twisted, and after a drunken spree he was seized with retention of urine. A medical man in town catheterised him with difficulty, lacerating the urethra considerably. From that time till four years since he laboured at various periods—when exposed to cold, or indulged in the use of alcohol—under attacks of retention of urine, which were always relieved by the use of opiates and warm baths.

Some years since he was admitted into hospital, under the care of my colleague, Dr. Murney, suffering from retention of urine. Dr. Murney, after several attempts, succeeded in passing a No. 1 probe-pointed catheter. He remained under treatment thirteen weeks, and was treated by the method of gradual dilatation. Before his leaving hospital Dr. Murney was able to pass a No. 9 bougie. Three weeks after leaving hospital the stricture commenced to contract, and in a few months the stream of urine was smaller than it had been previously.

Upon the 24th May, three days before his admission under my care, he had been drinking to excess, and was exposed to the cold; and upon the morning of the 25th May he was seized with retention of urine. Some medical man endeavoured to catheterise him, but failed.

He was admitted into hospital upon the 27th May, at 11 a.m. The house-surgeon gave patient a warm bath and an opiate. At the expiration of an hour, no urine being voided, the house-surgeon and pupil on duty each endeavoured to pass a catheter, but without success, a quantity of blood flowing from the urethra. He was ordered a warm bath, and liq. opii sed. zss every four hours. The opium was continued until 7 grs. had been taken.

At 2 p.m. I visited the patient, and found the bladder distended above the umbilicus. He was suffering great agony; pulse, 120; temp., 101°. I ordered the rectum to be packed with ice, and to take tinct. ferri perchl. mins. xx. every half hour. At 4 p.m., patient suffering great pain, no urine has been voided; the ice in the rectum had to be discontinued, as it produced great depression. I now tried to pass a catheter, but failed. Dr. Murney met me in consultation at 4 30 p.m., and chloroform being given, he endeavoured to catheterise patient, but failed. The man was suffering greatly, the bladder fully distended; and taking into account the man's previous history, I feared that, as he was probably labouring under organic disease of the kidneys, uræmic symptoms might arise, and owing to the strong spasmodic efforts of the bladder, rupture of that viscus would occur. Dr. Murney agreed with me upon immediate action, and at his suggestion I performed the supra-pubic operation for tapping the bladder, and drew off three and a half pints of highly-coloured urine. I tied the canula in the bladder, and ordered gr. 1 of opium every fourth hour. Beef-tea and milk ad libitum.

27th May (evening).—Pulse, 75; temp., 100.4°; patient greatly relieved; has slept some; urine to be drawn off every fourth hour.

28th.—Pulse, 78; temp., 100.4°; patient under the influence of opium; slight tenderness upon pressure over the right and left iliac regions. Continue treatment, with the addition of linseed meal poultices over the abdomen.

29th.—On arriving at hospital my resident pupil informed me that three hours previously the canula had been removed from the bladder, but by whom I could not ascertain—the patient blaming the nurse, and the nurse stating the patient had removed it. However, at 9 30 a.m., out it was. Upon examination I found a diffuse redness over the region of the bladder. The patient complained of a burning pain in the pelvic cavity; pulse, 120, and very weak; temp., 101°; evidently urinary extravasation had taken place. Dr. James Moore saw patient in consultation, and he also tried the catheter, but failed. Continue opium and linseed poultices, and have a warm bath. At 3 30 p.m. the patient was

¹ [Dublin Journal of Medical Science, 1877, v63, p191.]

very weak, and the diffuse redness over the abdomen had become extensive. I determined to get into the bladder by some means.

Three methods presented themselves:—(1). Puncture through the rectum. (2). Opening the membranous portion of the urethra through the perinæum. (3). Endeavour to pass a catheter through the abdominal puncture into the bladder.

Taking into account the man's debilitated constitution, and, as I said before, the probability of organic disease of the kidneys, I at once discarded the idea of perineal section. I first very gently tried to pass a catheter into the bladder through the abdominal wall, but failed in finding the opening in the bladder. I now determined to puncture the bladder through the rectum, which operation I performed in the usual manner with Cock's trocar and canula. Drawing off ten ounces of highly-coloured urine, I tied the canula in the bladder.

He was ordered gr. 1 of opium every four hours; linseed meal over the abdomen, and brandy ʒss. every hour, with milk ad libitum. Evening.—Pulse, 134; temp., 102°; diffuse redness over the right flank, and slight pitting upon pressure. Two free incisions were made, giving exit to some fluid possessing a strong urinous odour.

30th.—Pulse, 127; temp., 101°; abdomen tender upon pressure. The diffuse redness has now extended to left iliac region; it is much less upon the right side.

31st.—Pulse, 116; temp., 100°; tenderness all over the abdomen. Some urine flowed to-day per urethram, and a little per rectum, by side of canula; diffuse redness not so extensive, but of a darker hue.

1st June.—Pulse, 110; temp., 102°; complains of less pain upon pressure over the abdomen. Drew off eight ounces of urine through the canula, having a highly alkaline reaction, and containing a large quantity of mucus. Some urine passed per urethram to-day.

2nd.—Pulse, 100; temp., 100.2°; tongue furred; tenderness over abdomen increased; complains of pain over region of bladder, and along the dorsum of the penis, which is inflamed. The canula was withdrawn to-day.

3rd.—Pulse, 100; temp., 101°; passing urine, one tablespoonful at a time, every half hour; pain and redness around the abdominal puncture; matter is evidently forming.

4th.—Pulse, 98; temp., 100°; pus flowing freely from the abdominal puncture; urine comes more freely per urethram. Ordered the wound in the abdomen to be syringed with Condy's fluid. Bowels constipated; ordered a stimulating enema.

5th.—Pulse, 100; temp., 98°; had my attention drawn to-day to an abscess which had been slowly forming over the region of the right pectoral muscle; urine coming pretty freely per urethram; patient's expression greatly improved.

I need not detain the members by a detailed account of his daily progress. From June 5th he suffered from constipation of the bowels, which was relieved by enemata. Upon the 13th he was seized with diarrhœa, frequently passing ten and twelve fluid stools in the twenty-four hours. Nearly every remedy in the Pharmacopœa was tried to check the diarrhœa, which eventually yielded to a mixture containing acetate of lead, acetic acid, liq. morphia, and tannic acid. He complained frequently of tenesmus of the lower part of the rectum, and a peculiar burning pain. This was relieved by an enema of liq. bismuthi and starch. His pulse varied greatly during his illness, as also did the temperature. The general average of the pulse was 115, and the temp. 101°.

The abscess over the pectoral muscle, upon the 19th June, was found extending downwards; in a few days it got into the sheath of the rectus abdominis, and eventually discharged itself at the umbilicus. Upon the 24th June I succeeded in passing a No. 4 gum-elastic catheter into the bladder, which I tied in and retained. In the course of twenty days I was able to pass a No. 11 bougie. All urine had now ceased to flow per rectum and through the abdominal puncture. The patient during his long illness was, fortunately, able to take a fair amount of nourishment, which consisted of milk, eggs, and brandy. Upon the 7th August he was discharged from hospital, passing urine in a good stream, and feeling wonderfully strong. I saw this patient upon the 8th November, 1876; he was then able to get about the house, and walk a distance of half a mile. The umbilicus looked red and inflamed; the wound in the abdomen had quite healed; no urine coming either through the abdominal puncture or per rectum.

The members present congratulated Dr. Browne upon the success of his case.

Richard Ross

1876–77.

Third Meeting Tuesday 19 December 1876

Present, 17. Drs. Ross (President), Wheeler (Ex.), John Moore, McKeown, Wales, F. Beck, Dempsey, Pirrie, Stratton, O'Malley, J. W. Browne, Fagan, Spedding, Esler, Coates, Murney, Whitla (Secretary).

The following resolution was proposed seconded and carried. "That having heard with very great sorrow of the melancholy death of Doctor John McCrea we hereby recorded our sincere sympathy with those friends who mourn the demise of one whose life was so valuable and whose removal from our midst is felt to be such a loss not only to his relatives but to society generally and more especially to the Medical Profession of which he was a distinguished member. And especially do we desire to express our deep sympathy with Mrs McCrea and her children who have been so suddenly bereft of a loving husband and affectionate father."

The Secretary was requested to forward to Mrs McCrea a copy of the above.

Dr. McKeown gave a most instructive and able description of operation for trichiasis and entropion describing and figuring a new operation which he had adopted with success.

Paper:¹ Dr. McKeown stated that the observations he was about to make were meant to refer only to those forms of trichiasis and entropion which resulted from cicatricial changes in the conjunctiva, so common in granular ophthalmia. He commented on various operations—the operation of scalping, or, in other words, cutting off the margin of the lid with the roots of the hairs, he considered to be now no longer a legitimate operation, as we had a choice of several methods which were conservative and not destructive. The destruction of odd hairs by caustic or cautery should not be thought of, as, in the contraction of the tissues which ensued, other hairs would probably be caused to deviate. The endeavour to correct the intertwining of the hairs on the margins of the lids by removing a piece of the skin of the lid, so that the contracted skin would act as a counteracting force to the contraction of the conjunctiva, was generally most unfortunate in the end. The contraction taking place on both the outside and inside of the lid usually brought about a diminution in the depth of the lid, and when this took place to any considerable extent, the lid ceased to be a sufficient cover and protection for the eye during sleep. It was usually only by a great loss of skin that sufficient “tilting” forwards and outwards of the margin of the lid could be secured. He referred particularly to Arlt Jaesche’s operation, which consisted in detaching a very narrow strip of the outer margin, containing the cilia, leaving only a narrow attachment at the inner and outer canthus, and then transplanting this band to a higher level on the lid, the way being prepared for this change of position by the removal of a semilunar fold of skin adjacent. It was well known that this operation was very satisfactory in the great majority of cases; but it was acknowledged to have some drawbacks—viz., 1st. The liability of the narrow band to slough, in consequence of its two very slender connexions with the rest of the lid; 2nd. The loss of skin; 3rd. The very protracted and painful character of the operation. Dr. McKeown then demonstrated a mode of operation free from all these objections, and which consisted in the fact of gliding the whole skin of the lid with the hairs upwards, whilst the tarsal cartilage and conjunctiva were pulled downwards. In Arlt’s operation there is, on the contrary, the transplantation of only a narrow band. The operation is performed as follows:—The lid being supported and made tense, by a flat horn protector, introduced between it and the eye-ball, the operator enters Graefe’s narrow knife at one extremity of the lid, at the margin between the cilia and

Meibomian ducts, and pushes the knife vertically into the lid as far as he can conveniently, and then cuts along to the other extremity of the lid, still following the line between the cilia and the Meibomian ducts. The point of the knife must not be made to emerge through the skin. In this way the lid is completely split, and the two layers will glide freely on each other. The next step of the operation consists in passing through the tarsal cartilage, which is contained in the conjunctival layer, three strong threads, one at the middle point, and the two others near the outer and inner extremity, respectively, at the distance of about a line or a line and a half from the margin. By means of these threads the cartilage is pulled down towards the cheek, and, when sufficient traction has been made, the threads are to be attached to the cheek securely by adhesive plaster. After the first strip of plaster is placed over the threads, the ends are to be turned up over the plaster and another strip superposed. In this way the threads will not slip. A strong thread is then passed through the outer or cutaneous layer, not far from the cilia, its point of entry and exit being both in the skin, and at equal distance from the hairs. By this thread the skin layer, with the hairs, is drawn up, and then the thread is secured to the forehead by plaster. A little nicety is required in so inserting this thread and making traction that the hairs may be tilted outwards and upwards, and raised sufficiently, but a knowledge of this can only be attained by experience and a careful observation of each operation. The degree of separation between the margins of the outer and inner layer can be regulated at the will of the operator. It is well to have a separation to the extent of two lines at the least. As regards the thread passing through the skin layer, it is advisable not to allow it to remain more than two or three days, whilst those passing through the tarsal cartilage may remain several days longer. The insertion of the threads is an essential in this operation. If not done, the elevator of the lid, which still remains attached to the tarsal cartilage, would, in all probability, draw the cartilage up inside the skin layer, so that the hairs would be just as badly placed as before. The operation may be modified in various ways. For instance, in thickening of the cartilage and deformity, the cartilage may be grooved, pared, or otherwise dealt with, as Streatfield and others have proposed. Dr. McKeown concluded by stating that he frequently operated in the manner described, and always with the best results. The operation might be performed in a few minutes, whilst for Arlt Jaesche’s half an hour or upwards was required. No skin was removed, and, consequently, there was no scar, and no tightening or contraction of the lid. Sloughing was not to be dreaded as in Arlt Jaesche’s operation, as both the cutaneous and inner layer had most extensive vascular connexions with the adjacent parts. And, finally, when the healing process is completed, it would require a practised eye to detect that anything had been done.

¹ [Dublin Journal of Medical Science, 1877, v63, p297.]

Dr. Murney said he had operated by the older methods, especially by that of Arlt. The operation now described was entirely new to him. He approved of the principle.

Dr. M. Moore had been present at some of the cases while Dr. McKeown operated. He was glad to hear of their success, and thought the operation a great improvement. It was simple, expeditious, and highly satisfactory; and, were he called to operate himself, he would decidedly follow Dr. M'Keown's plan.

Dr. J. W. Browne had considerable experience in operating for trichiasis and entropion, which he did by the older methods. As regarded the operation described, he had seen Dr. Perceval Wright operate by a method which seemed to him very similar to that of Dr. McKeown, about nine years ago.

Dr. Wales was pleased with the ingenuity of the operation. He thought it was a decided improvement upon the older methods.

Dr. Wheeler commented upon its principle, which he thought was a sound one, and must be followed with a better result than the more elaborate and complicated operations.

Dr. Ross (the President) endorsed the remarks of the members present. To him the operation seemed a decided success. He reviewed the older operations, and agreed with Dr. M'Keown.

Dr. Esler said that, having had the advantage of being a former pupil at the Eye, Ear, and Throat Hospital, he had seen Dr. M'Keown's method of operation carried into practice, and could bear testimony to the fact that it was expeditious in the performance and highly successful in its results.

Dr. Murney read notes of a successful case of ovariectomy (operated upon in the Royal Hospital) and exhibited the cyst which he had removed.

Paper:¹ Dr. Murney described a case of ovariectomy, performed by him on the 23rd November, resulting in recovery, the wound being almost entirely cicatrised, and the patient out of bed on the 24th day from operation.

The leading facts of the case were:—A widow, aged thirty, otherwise healthy looking, who had never been pregnant, seven years since noticed a small movable tumour in the left side of the abdomen. From May, 1876, this rapidly enlarged. Early in October she had acute pain in the abdomen, which continued for several days, and which compelled her to seek admission into hospital. For some time prior to operation the pain had subsided, but the abdomen was so large she could not approach the recumbent posture.

23rd. Nov.—The patient having been chloroformed, an incision was made from a short distance below the umbilicus to about one-half inch above the pubis. On exposing the tumour its anterior surface was found to

be adherent to the parietal peritoneum. These adhesions were broken down by the finger and the sac punctured by the canula. Twenty pints of the usual ovarian fluid were drawn off. The diminished mass was now readily drawn through the wound, as there were no adhesions binding it posteriorly. A Liston's needle, armed with dentist's silk, was passed through the pedicle (which was short) and the two ligatures tied, then another ligature was carried round the two, the pedicle cut, and the uterus allowed to fall back into the pelvis. The ends of the ligatures were carried out through the lower part of the wound. The right ovary was healthy. Six sutures brought the incision together. A pad of lint, saturated in carbolic oil, laid on, then a dry pad and a flannel roller. A suppository of half a grain of hydrochlorate of morphia administered, and repeated at bedtime for eight days, when one quarter grain was used for four nights. After this no further anodynes were required.

	Temperature		Pulse	
	9 a.m.	9 p.m.	9 a.m.	9 p.m.
23rd Nov., ...	98.4°	100.8°	86	92
1st day, ...	100°	100.8°	104	120
2nd day, ...	99.2°	98.4°	110	115
3rd day, ...	99.2°	99.2°	108	100
4th day, ...	98.2°	98.4°	100	100
	Normal afterwards. Steadily came down.			

Measurements of Abdomen.

	Before Operation.		After.
	30 days	5 days	26 days
Circumference at umbilicus,	39½	41	28
Pubis to umbilicus,	7½	9	4½
Pubis to ensiform cartilage,	17	19½	10
Umbilicus to ensiform cartilage,	9½	10½	6
Umbilicus to anterior superior spine, on each side,	9¾	10½	5

On the fourth day there was slight action of the bowels without medicine.

On the fifth two sutures were removed, and menstruation commenced and continued for three days.

On the sixth the remaining sutures were taken out.

On the twentieth the ligatures came away.

On the twenty-fourth she was out of bed for the first time.

In addition to the large sac containing the fluid which was drawn off, the tumour was made up of four other sacs, small, and the contents were much more viscid and much more opaque than the first mentioned.

¹ [Dublin Journal of Medical Science, 1877, v63, p291.]

Dr. J. W. Browne congratulated Dr. Murney upon what he said was the first known case of ovariectomy in the North of Ireland. Other cases, he believed, had been successful; but this was the first published one. He detailed two fatal cases in the Belfast Royal Hospital. He approved highly of the details of the operation, which he would exactly follow, were he called on to operate.

He censured Dr. Wells' trocar and canula as a delusion. He saw it used in three cases, and in all it failed in its object. He did not think that tapping a few days before the operation would lessen the shock to the patient's system, nor did he think it would facilitate, in any way, any step of the operation.

Dr. John Moore, in congratulating Dr. Murney upon the success of his operation, referred to the successful case of Dr. Thompson of Lisburn—the first, he stated, in the province of Ulster. He had thought this a most suitable case for operation, and so it had turned out. As regarded tapping, he thought that tapping before operation would prevent the surgeon distinguishing between the cyst and the peritoneum—a most important point. He was present at the operation, and would say there was not a detail upon which he thought he could improve. Drs. Stebbing and Wheeler saw no advantage in tapping.

Dr. McKeown reviewed the history of the operation, and referred to the great success of Spencer Wells and others. As regarded the remarks of Dr. Browne, he thought that when a man of such vast experience in ovariectomy as Wells—experience which could not be hoped to be within the reach of any present—approved and used constantly in his practice any instrument, he thought they were called upon to follow him.

Dr. Fagan congratulated Dr. Murney, not so much on the success of his operation, as for his superior diagnostic powers, which were well shown by his selection of so suitable a case for operation. The mere mechanical quality of doing an operation well, was, he held, no test of true ability in a surgeon, while acute diagnostic powers entitled him to the highest rank. Why it was that many operations of great merit had fallen into disrepute was, he believed, due to the bad selection of cases for operation—not to the operation itself. He was present at an operation for ovariectomy a few years ago at a London hospital. The patient was under the operation for two hours or more. The cyst was adherent throughout. The surgeon, in the most dexterous and fearless manner removed it, and the patient died two hours afterwards. It then occurred to him had the surgeon been as acute in diagnostic powers as he was dexterous and fearless in the use of the knife, he would have rejected it as unsuitable for operation. The opening of the abdominal cavity should not be considered, as it usually was, so formidable an operation. He saw every week in the journals reports of successful cases of abdominal section for cases of intussusception, of ovariectomy, and, occasionally, of Cæsarean section. When

suitable cases were selected, and ordinary care taken in its performance, he believed ovariectomy should not be attended with much more risk than ordinary amputation.

Dr. Whitla (Secretary) did not approve of the theory of tapping a few days before the operation to lessen the shock. He narrated three instances where serious collapse followed tapping, and on the third day alarming inflammatory symptoms supervened from incomplete evacuation of the contents of the cyst. Many such cases were published by Mr. Wheelhouse of Leeds, and he thought it unjustifiable to subject the patient to a double risk, but he approved of tapping as an aid to diagnosis.

1876–77

Fourth Meeting Tuesday January 2nd 1877

Present, Drs. Ross (President), Wales and Browne (Vice-Presidents), Fagan (Treasurer), Whitla (Secretary), Murney, Grattan, Core, Coates, Esler, McIvor, Pirrie, Strahan, Spedding.

A ballot was taken and Dr. Adam Reid and Dr. McIvor were elected.

Dr. Fagan read notes of a case of malignant tumour of the orbits and illustrated it with water drawings and photographs.

*Paper:*¹ Daniel Macklin, a young anæmic child, aged seven years, was admitted under my care at the Children's Hospital on the 13th October. He was suffering from diarrhœa at the time, and was delicate for four or five months previously. There was a tumour on the left temporal region, limited by the boundaries of that fossa. The eye was protruded and ecchymosed, and he sometimes complained of it as being painful and itchy. The only history I could get in connexion with the case was that, about six weeks previous to my seeing him, the eye was noticed to be somewhat more prominent than its fellow, and the temporal region somewhat fuller than the opposite one. The only cause the parents could assign for this condition was that, a short time previously, while hammering something with a poker, it rebounded, giving him a sharp blow on the temple. It caused acute pain at the time, but did not afterwards trouble him. Careful manipulation of the swelling conveyed an indistinct sense of fluctuation, as if matter existed deeply in the tissues. This was my diagnosis at the time, and it was confirmed by some other medical men who saw the case with me. That it was a case of deep-seated chronic abscess I considered most probable for the following reasons:—First, the history of the case would point to the blow on the temple as being the exciting cause; next, the symptoms following might be those of inflammation, of a sub-acute form, of the deep cellular tissue, the matter formed being bound down by the dense structures in the temporal region, made its

¹ [Dublin Journal of Medical Science, 1877, v63, p380.]

way through the parts that offered least resistance. This I believed to be through the sphenomaxillary fissure into the orbits. This condition of things, I satisfied myself, could account for the protrusion of the eye-ball and the swelling in the temporal region. Accordingly, after a few days, when I got the lad's health into a better state, I put him under the influence of ether, and made an incision over the great wing of the sphenoid, right down to the bone. Nothing came away but a little blood. I then passed a narrow-bladed knife along the outer wall of the orbit, back into the sphenomaxillary fissure, and with the same result. Water-dressing was applied, and the lad put back to bed. No bad effects followed the wounds made in exploring the parts. They healed up in a few days. When I satisfied myself that the swelling was not due to an abscess, I was inclined to look on it as malignant. The only treatment I now employed was to protect the parts, keep them clean, and support the child's constitution. The temporal enlargement went on steadily increasing. The eye-ball became still more protruded, the conjunctiva very vascular and swollen. The cornea, at first clouded, became ulcerated, and covered with crusts of dried secretion; the tears flowed over the cheek, and were of a dirty, muddy character. He slept pretty well, and eat well, and complained only occasionally of pain. This was his condition on the 29th, about a fortnight after his admission, and at this time I noticed a swelling in the right temporal region, of the same character as the other, in its earliest stage. In two or three days this increased, and the right eye-ball began to protrude. I had now no doubt about the malignancy of the affection, and acquainted the parents of the hopelessness of the case. The child was removed home, and I did not see him until November 20th, when I got photographs taken. He then presented the appearance that is pretty well shown in the likeness—that is, the former condition of parts very much aggravated. He appeared completely broken down in constitution, and exhibited in his appearance what is supposed to be the characteristic cancerous cachexia. His appetite was bad; he became peevish and irritable; his sleep was restless and irregular, and he sometimes awoke with a scream. Three days before his death he got a short, teasing cough, the lower extremities became œdematous, and he complained of difficulty of breathing and pain about the chest. He died on the 9th December.

This case, Mr. President, I have found to be most instructive. It shows that no matter how careful the surgeon may be in considering the causes and symptoms, he may be mistaken in his diagnosis; and, what is of more importance still, he may hold out hopes, or predict gloomy results, only to find himself and his patient disappointed in the end, or, taking hasty action on his decision, he may cause an unnecessary sacrifice of parts. In this particular case the action taken on the diagnosis could not in any way leave it in a worse con-

dition, while it assisted very much in throwing more light on the subject. The importance of forming a correct diagnosis is more evident when one of the limbs is the subject of a similar tumour, and that the question of amputation has to be taken into consideration in its treatment. Mr. Holmes, in speaking of the difficulty of establishing a diagnosis between ostitis and malignant disease, says that he has known at least three cases in which amputation at the hip-joint had been contemplated for a malignant affection of the femur, which turned out afterwards to be of a simple inflammatory nature. And after going over the various symptoms that aid one in their diagnosis in such cases, he says one practical consideration must occur to the mind of anyone charged with the responsibility of a case of this kind—viz., that no operation ought to be performed while any doubt whatever rests on the diagnosis. If the case is one really of cancer, the operation is, at the best, of doubtful value; if it is ostitis, it be worse than superfluous. Dr. J. W. Browne said he had the advantage of seeing the patient, and when he saw him he thought it was a case of abscess at the back of the orbit, pushing forward the eye-ball, and that it was the result of the injury, which was so clearly stated by the parents.

He said there were cases narrated by Mackenzie and others where soft cancer (encephaloid disease) had immediately followed injury. He considered this case one of these, and pointed out the resemblance between this and strumous disease, the differential diagnosis between them being that in cases of strumous disease, where the eye-ball bursts, it collapses, while in the encephaloid it increases in size. The disease had probably commenced in the brain or ethmoid bone.

Dr. Dempsey thought that if the disease had commenced in the brain cerebral symptoms would have shown themselves.

Dr. Wales saw two cases of cancer in young children of cerebral origin. In both death resulted from secondary deposits—in one in the thoracic, and in the other in the abdominal viscera, and in both cases no cerebral symptoms showed themselves, the children remaining clear till the end.

Dr. Coates thought if this was a case of cancer, it was certainly most unusual in one so young.

Dr. Whitla said Dr. Fagan had referred to the use of the ordinary hypodermic syringe which he (Dr. Whitla) had tried in this case to clear up the diagnosis. He had used it often, and never saw it fail to detect pus in any case where the after-course showed there had been pus. He saw it recommended first for the diagnosis of fluid in the pleura.

He used the syringe in this way—after seeing the piston was air-tight, he half filled the cylinder with water, introduced the needle into the suspected abscess, and injected three or four drops of water to clear the needle, then a few turns of the screw brought the pus ascending through the clear water in the cylinder. He

thought that, in ordinary practice, it was vastly superior to the aspirator. The needles which he used he had made by Gardner of Edinburgh. They were of extreme fineness, and caused little pain.

Dr. Murney exhibited a compressed fracture through the knee joint of three months standing removed the week before. The man was progressing very favourably.

Paper:¹ Dr. Murney exhibited a specimen taken from a patient who had sustained a compound comminuted fracture through the knee-joint three months ago, by the falling of the framework of a ram. The injury was followed by intense collapse, in which condition he was admitted into hospital, and it was the unanimous opinion of the surgeons that it would be unwise to amputate, the patient was so low.

In this condition he remained for some days; and when the question of secondary amputation came to be considered, he was so prostrated by the profuse discharge which poured from the wound, as well as by a most obstinate and wasting diarrhoea, night-sweats, and loss of appetite, that the question of operation could not be entertained till about three weeks ago, when he amputated by Carden's method, and the patient made an excellent recovery, being now nearly convalescent.

The specimen showed that the patella was removed, and the section made through the lower-third of the femur at its junction with the middle one-third. The fracture was T-shaped. The inner condyle of the femur was detached, the outer was externally rotated, and partially united to the shaft. The knee-joint was found partially ankylosed, being united by a kind of fibrous or ligamentous union, and which never could have been of any service to him. Three or four pieces of bone exfoliated, and became sources of great irritation.

Dr. Fagan asked if the fracture had been diagnosed at first as passing through the joint; if so, after the shock had passed off, he thought primary amputation should certainly have been performed. The fact of his surviving, and the after-history of the case, proved this. With Dr. Murney's remarks about tying large veins he quite agreed, but preferred torsion. He had twisted the femoral four times, and was pleased with the result.

Dr. Coates (House Surgeon) said the idea of primary amputation could not be for one moment entertained. The shock lasted for five days, during which he was fed upon stimulants.

Dr. Wales thought the case interesting from a medical point of view, and inquired was the liver enlarged or the urine albuminous?

Dr. Browne, who had seen the patient a few days after the injury, when he first came under his care, found the limb up in the long splint, which he at once

changed for Macintyre's. The liver was enlarged. Urine contained no albumen; discharge was profuse, and symptoms of pyæmia soon showed themselves. He was told amputation was out of the question from the first. The diarrhoea was most obstinate. He found lead and opium had some effect; but this soon produced drop-wrist, and marked the gums, and had to be discontinued. He was most anxious to amputate, but never saw a suitable opportunity. The patient then passed into the hands of Dr. Murney, and it was not for some time after this that any hope of a successful operation was entertained.

Dr. Ross thought the case had a very successful termination. He always looked upon the knife as an opprobrium; but, certainly, it seemed to him, in this case, that it had saved a life. He questioned very much the issue if the knife had been used at first, from the description which he had heard of the patient's condition.

Dr. Spedding read notes of puerperal convulsions the discussion on which was postponed till next meeting.

Paper:¹ THE coincidence of meeting with two cases of puerperal eclampsia within the same week, last summer, induced me to take notes of them at the time, with the view of bringing them before this Society. They are peculiarly interesting, inasmuch as they appear to be typical cases of the two great varieties of this disorder, the first being of the apoplectic kind occurring before delivery, and the other of the epileptic form occurring after the complete termination of labour.

CASE I.—On the morning of the 12th June I was called upon to assist Dr. Newett, of Ligonieil, in a case of difficult labour. Upon my arrival Dr. N. informed me that his patient, a very stout, plethoric woman, aged thirty-one, a primipara, had been about two days in labour, first stage, but that during the last twelve hours she had been in convulsions, which were at first tonic, but had then become less severe, although recurring at very frequent intervals. When I saw her she was in an insensible condition, with excessive muscular twitching; pulse about 140, and very feeble. The head was at the brim; the os rigid at the edges, but soft and thin all round. The only chance of the patient's life appeared in immediate delivery, but the modus operandi occupied our serious attention.

The os uteri would only admit the index finger to the second joint, and showed no signs of dilating. The state of the pulse put blood-letting out of the question; and remembering that craniotomy had a prejudicial effect in such cases, by exciting reflex action and thus increasing the paroxysms of convulsions, we decided upon incising the os sufficiently to enable the hand to be introduced for the purpose of performing podatic version.

¹ [Dublin Journal of Medical Science, 1877, v63, p382.]

¹ [Dublin Journal of Medical Science, 1877, v64, p175.]

I should here state that the bowels had been freely opened by doses of *pulv. jalap co.* and croton oil, and that the patient had been cupped upon the nape of the neck. I put her fully under the influence of chloroform, and Dr. Newett introduced a Lund's abscess knife within the os, and cut backward in the median line to the extent of about half an inch. He then gradually dilated the os with two and then three fingers. In about ten minutes he was enabled to introduce the hand, and he brought down the feet without much difficulty. The incision did not extend into the fundus, although great traction by the forceps was required to disengage the head. We left her free from convulsions, but semi-comatose, and with stertorous breathing, which continued for eight hours afterwards, when consciousness gradually returned, and I was gratified to learn that she made a good recovery within ten days, without the occurrence of any inflammatory symptoms. I should have said that before labour set in there was considerable œdema of the legs and face, and that the urine contained a large quantity of albumen.

CASE II.—On the 19th June last, I was hurriedly summoned to visit Mary Edmonds, a young woman, aged twenty-four, who had, I was told by the messenger, been delivered of her first child that day, about six hours previously. I found her in a severe epileptic convulsion, quite unconscious, frothing at the mouth, face livid, and having to be held in bed by three persons to prevent her falling out. The history I got from her sister was, that she had been always healthy, never had had any fits, and that she had an excellent confinement, being only ill three hours. The urine contained no albumen, and the only cause I could assign for the attack was, that the day before she slipped off the curb-stone and got a severe shake; afterwards she walked home somewhat frightened, and that night it brought on labour, about a fortnight before she expected it. I at once administered an injection of soap, warm water, and turpentine, in the meantime sending in haste for chloroform. The enema produced no apparent effect, the convulsion continuing with great severity for more than half an hour. I then put her under the influence of chloroform, which had a marked effect in controlling the convulsion. A second, however, succeeded the first, which only lasted ten minutes; and at the commencement of the third, I decided, in the extremity, of bleeding from the arm, inasmuch as the pulse was full, or rather bounding, and about 120. This I did to the extent of about 35 ozs., from the right median basilic vein. The fits continued, though severe, and only lasting a couple of minutes.

At 11 p.m. I met in consultation the medical gentleman who had attended her in her confinement the same forenoon. He had been out of town during the afternoon, and was much surprised and grieved at the untoward turn the case had taken, having, as he said, rarely attended an easier or more natural first case. We

placed calomel and croton oil on the tongue, which the patient could not swallow; ordered a fly blister to the nape of the neck, and sinapism to the chest and feet. She continued convulsed at intervals during the night, and died the following morning at 10 a.m., twenty-four hours after delivery.

With regard to blood-letting in the second case, I have to observe that, although it is not so generally recommended in convulsion occurring after delivery, I felt justified in trying it in this case, from the following reasons:—The character of the pulse, the absence of any post partum discharge, the fact that the patient was unable to swallow any sedative medicine, and especially from the fact that the anæsthetic had failed to produce any permanent effect. Monsieur Charpentier, of Paris, in a valuable thesis, written three years ago, endeavours to show that the mortality in this affection was thirty-five per cent, treated under the old treatment of general bleeding, and only eleven per cent, in those treated by anæsthetics, foremost amongst which ranked chloroform and chloral. The fact that doctors differ is well shown in the opinion of several eminent obstetricians on the question of prognosis in this affection—Paget, Blot, Dugés, and others asserting that eclampsia occurring after delivery is far more amenable to treatment than other forms; while Ramsbotham, Churchill and other eminent observers hold the very opposite opinion.

On these various subjects, which are pregnant with interest, I await with a degree of pleasure the views of the different members of this Society.

Richard Ross

1876–77

Fifth meeting Tuesday January 16th

Dr. Ross (President), T. K. Wales, J. W. T. Smith, J. W. Browne, John Fagan, Fred Beck, S. B. Coates, Pirrie, Strahan and Whitla—Secretary.

An extended discussion arose from Dr. Spedding's paper on "Eclampsia Puerperal" in which the members present joined after an opening speech from Dr. Ross. The remarks will appear in the transactions.

Paper:¹ The PRESIDENT opened the discussion with a review of the symptoms and treatment of the affection. He said that owing to the importance of early treatment too much attention could not be paid to the value of the premonitory symptoms, and foremost among these was headache. This headache he found was always severe and constant; it was to be noticed in a large percentage of all cases of puerperal convulsions; it was to be noticed, too, at an early date—often, indeed, before dizziness, motes, and other sensations complained of by the patient—next was seen œdema of the face and fingers, and albuminuria. The attack then supervened; at first, tonic contraction of the muscles of

¹ [Dublin Journal of Medical Science, 1877, v64, p177.]

the body followed by clonic convulsions, especially of the muscles of the face, and, after an interval of variable duration, partial obliteration of consciousness or coma, more or less complete. This condition of matters generally brought on labour, a process requiring for its satisfactory and safe termination that balance of all the forces found in healthy parturition. He was glad to state that the mortality had very considerably fallen since the practice of free blood-letting had fallen into disuse. As regards the pathology of the disease, there was great room for difference of opinion. He would direct attention, in the first place, to the state of the blood in pregnancy. All observers agreed, to the nature of its composition, that it was "watery," the well-marked anæmia of this condition being familiar to all. Secondly, he would remind them of the altered and increased arterial tension; and, thirdly, of the hypertrophy of the heart. Now, what did these three things produce? temporary cerebral congestion—the principal element in the disease. This afforded an explanation of how bleeding was sometimes beneficial; there was also œdema of the cerebral tissue, and this effusion pressed upon the vessels and finally produced anæmia of the tissue. He thought, then, that it was high time to give up the practice of bleeding, since it directly produced anæmia of the brain substance; he thought it might be possibly of good in some cases, but he never met such; and he thought the high rate of mortality was chiefly, if not solely, owing to this practice. His own treatment consisted in free and speedy purgation; the form of purgative he found most suitable was that which acted most speedily and efficiently, and he gave it in large and repeated doses. As regards the use of chloroform, he highly approved of it in some cases, and the rule which guided him in its administration was, to wait for threatening convulsions, and anticipate them with the anæsthetic. Chloral hydrate he found very useful sometimes, especially in the post partum variety of eclampsia. Hypodermic injection of morphia he had used, and seen used with good results, its chief advantage being the rapidity of its action, and the ease with which it could be administered. The most important and serious part of the treatment was, what to do with the uterus and its contents. He would say, rupture the membranes, and induce by all means speedy contraction of the organ; he did not like to interfere with the os. The best rule, he thought, that could be laid down for this part of the treatment was, as soon as possible, to empty the uterus.

DR. F. E. BECK said he never bled in convulsions coming on, during, or after labour. He had seen cases where this treatment was adopted, and it seemed to him with anything but good results, so that he never did intend to extract blood. As regarded the pathology of the disease, he believed in the reflex theory, which seemed to him the most rational and satisfactory. He had now attended upwards of 4,000 cases of labour containing

several (he did not recollect how many) cases of puerperal convulsions, and, he was glad to say, he never lost a case from this disease. He believed in purgatives, and in watching for symptoms; if we looked out in every case for the first warnings of the attack, our treatment, he believed, would be much more satisfactory and successful.

Dr. J. W. BROWNE said he believed the pathology of the affection was almost entirely identical with that of Bright's disease in the acute stage. Doubtless, very good authorities differed from this—a circumstance which lead him to believe that there might be two classes of the disease. He detailed some cases which he thought supported this view, one of which the ex-President, Dr. Wheeler, had seen with him. He hardly thought he could say that bleeding was unsuitable in every case. Doubtless, recoveries were recorded. The difference in the mortality did not necessarily depend upon the disuse of the blood-letting; in some hands it was succeeding even yet.

Dr. J. W. SMITH said that the President had not referred to the uræmic theory of puerperal convulsions. No doubt, cases of this affection, when no albumen has been found in the urine, had been recorded, and he supposed it was to such that the theory advocated by the President referred. Although he did not deny the occasional occurrence of such cases, he looked upon them as exceptional and comparatively unimportant. In his own experience he had met with no case in which the urine did not contain a large amount of albumen, and was also scanty. He believed that, in the great majority of attacks of puerperal eclampsia, the kidneys were in a state of passive congestion, or in a condition very similar to acute Bright's disease. This condition he looked upon as resulting from the mechanical pressure produced, by pregnancy, on the renal veins and inferior cava. In support of this opinion he referred to the fact of the frequency of eclampsia in primiparæ when the parts are resistant, and to the fact, that the albumen does not appear until the later period of pregnancy, when the pressure on the veins is greatest. He had seen cases in the later months of gestation where, the urine being scanty and albuminous, intense headache and slow pulse appeared to indicate that convulsions were imminent, and where they were averted by free purgation, mustard poultices to the loins, and such other treatment as would be adopted in similar conditions in Bright's disease. As regards the cases which had been brought before the meeting, and which had originated the discussion, he could not agree with the treatment pursued. He certainly believed that in all these attacks it was desirable to empty the uterus with as little delay as possible, but in many cases labour had not yet begun, or had but little advanced, and a precipitate attempt to deliver would be attended with great danger both to mother and child. Bloodletting had been recommended in these cases by many eminent authorities, but he

never used it, and had no reason to regret that he had not done so. He had lately seen three cases in consultation. In the first the patient had suffered from convulsions in her first pregnancy. She again became pregnant, and at the end of seven months anasarca appeared with albuminous and scanty urine. Two days afterwards convulsions set in, but no sign of labour. The bowels were freely opened, the membranes ruptured, and chloral given by enema. The fits recurred at longer intervals and ceased entirely 36 hours before the birth of a living child, which took place three days after the first convulsion. The urine of this patient was repeatedly examined after her first pregnancy, and was quite free from albumen. In the second case the patient's urine became albuminous in the last month of pregnancy, and she had a convulsion soon after labour commenced. The bowels were acted upon, and the membranes ruptured; there was no recurrence, and she was delivered in a few hours of a living child. In the third case the patient, when seen, was comatose, and craniotomy was performed. The convulsions continued for several hours after delivery and then ceased, the patient becoming quite conscious and promising a good recovery, but congestion of the lungs set in on the 4th day, and death occurred in 48 hours. Albumen, no doubt, was occasionally found in the urine of pregnant women, and no evil results followed, but he had seen no case of puerperal convulsions when it was absent from the urine.

DR. T. K. WHEELER agreed with Dr. Smith. He had seen no case of puerperal convulsions in which there was not more or less albumen in the urine, generally a large amount, and he, therefore, believed that the kidneys were at fault in many, if not all cases. His first case occurred about 25 years ago; he had met many since then, and all were primiparæ except one. He detailed the particulars of a patient who had convulsions in one labour, and next time showed all the symptoms—albuminuria, anasarca, &c., but with free purgation no convulsions followed. His experience was altogether against blood-letting; he became early influenced in this way by hearing a paper which the late Dr. Pirrie read before the Society many years before. His practice was to induce labour, losing no time in having the uterus emptied, and he purged freely. Of the various drugs which he had tried with this intention, he had given all up for croton oil—it was the safest and speediest, and by far the most effectual. The form in which he generally administered it was:—2 drops with 1 drachm of compound jalap powder in 8 powders; 2 immediately in wafer paper, and the remainder to be given as circumstances indicated. These he looked upon as the main points; then the administration of chloroform, as the President had recommended, he found very useful in modifying the frequency and force of the convulsions. Believing that the explanation of the eclampsia lay in its uræmic character, and that the convulsions

only occurred when the urea was changed into carbonate of ammonia, he had tried tartaric acid as an antidote, and was sometimes struck with the rapidity of its action, but it was not to be relied on. Benzoic acid he thought more favourably of; in addition to its acid reaction, it stimulated the renal organs, and in that way often proved very beneficial.

DR. WHITLA (Hon. Secretary) had heard the remarks of the President with interest, especially those touching upon the pathology of the disease, which, however, he did not agree with. But he thought it a step in the right direction, as he had not once referred to the kidneys. There were few diseases or conditions upon whose pathology a greater variety and difference of opinion existed; indeed, in looking over the history of the subject he found that most of the organs of the body had been, at one time or other, seized upon as the parts at fault.

Excluding those cases where pregnancy supervened upon Bright's disease, much, he thought, yet remained to be learned. He had satisfied himself that a study of the functions of the liver would throw much light upon many such cases. The albumen of the food, after its absorption, must be changed into colloid albumen, else it will pass out of the vessels as readily as it gained admission into them—in other words, crude albumen must be assimilated to the albumen of the blood, otherwise it cannot circulate with it, but is instantly picked out by the kidneys, and washed away in the urine. This assimilating process takes place in the liver. Now, anything which interferes with this function of the liver prevents the albumen undergoing the necessary change, and determines its appearance in the urine, where it is readily detected, leading constantly to the conclusion that these organs are the seat of the disease; while, if rightly interpreted, he thought it was but evidence that they were fulfilling their function efficiently. In puerperal eclampsia were seen the very conditions which would be expected to disturb the functions of the liver, especially in first cases. Speaking of the actual cause of the convulsions and coma, he referred to a paper which he read before the Society upon "Uræmia in Liver Affections" (Dub. Monthly Journal February, 1876).¹

The liver manufactured the urea out of the effete products of wear and waste, the office of the kidney being merely to throw it out after its elaboration. Consequently, when this function of the liver was deranged, these products were not reduced to urea; but the process stopped short, and intermediate compounds—tyrosin and leucin—were formed, substances which the kidney could not so easily eliminate, and which, therefore, accumulated in the blood and gave rise to symptoms similar to poisoning by urea, from which substance, in chemical composition and physiological

¹ [Page 1237.]

effect, they differed little, and might practically be regarded as modifications, possessing lesser solubility. In respectfully submitting this theory to the consideration of the Society, he ventured to hope that they would see in it a satisfactory explanation of some cases of puerperal albuminuria with convulsions otherwise difficult to clear up. As regarded the difference of opinion about treatment, this might be explained—one authority strongly condemning bleeding as almost certain death, while recommending copious and excessive purgation. He saw no difference in such cases; one bleeds by the bowel, while the other opens a vein, and good results might follow each. Either would effectually help to unburden a loaded liver in its action.

On the motion of Dr. Wheeler seconded by Dr. Ross, the following Microscopic Committee was appointed: Dr. J. W. Browne, Fagan, Coates, Wales, Core and Whitla, the latter to act as convener.

On the motion of T. K. Wheeler seconded by J. W. T. Smith, Professor Cunningham was proposed as an Honorary Member of the Society.

Dr. Fagan exhibited a patient upon whom he had operated for disease of the tarsus. He postponed reading the notes of the case till next meeting.

Richard Ross

Session 1876–77

Sixth Meeting 30th January 1877

Present, Drs. Ross, Wales, Moore John, Dempsey, Coates, Core, Esler, Whitla, Spedding, F. E. Beck, Dr. Johnston

The question of an election of an Honorary Member (Professor Cunningham) was discussed and it was the wish of majority of the members present to postpone his election to next meeting when Professor Redfern, proposed by Dr. Esler, should be balloted for at the same time. In the meantime the Secretary was directed to look for any rule bearing upon the subject.

Dr. Pirrie and Dr. McKeown whose names appeared in the circular (convening the meeting) for the reading of papers did not present themselves at the meeting.

Dr. J. W. Browne read notes of a case (treated by silver wire sutures) of fracture of the lower jaw.

Paper:¹ J. M., a carpenter, aged twenty-two years, was received into the Royal Hospital under my care upon the 25th September, 1876, suffering from a double fracture of the lower jaw, caused by a blow which he had received during a drunken row ten hours previous to admission.

Upon examination the house-surgeon found that there was a double fracture—one being vertical, and upon the left side of the jaw, and close to the symphysis; the other oblique, and situated at the angle of the right side. The mucous membrane in the neighbourhood

of the angle was extensively lacerated, and there was constant bleeding from this point. The tissues over the region of the hyoid bone and thyroid cartilage were swollen and tense. The patient complained of great difficulty in swallowing, and breathing was much impeded. The right side of jaw was depressed; the teeth hung one inch below the level of the teeth upon the opposite side. The hæmorrhage was checked by the local application of tinct. ferri, and evaporating lotions were ordered to be applied over the upper part of the neck and face; he was also ordered a mixture containing sulphate of magnesia, tartar emetic and liq. morphiæ. No splint or bandages were used to keep the fragments in position, as the most trifling pressure caused a sense of suffocation.

During the following six days there was high inflammatory fever and severe constitutional irritation. The respiration was seriously affected—so much so that I told the house-surgeon to be prepared to perform tracheotomy. Upon the eighth day I endeavoured, by means of the usual gutta-percha splint, to get the fragments into position, but without success, as the patient was still unable to bear the slightest pressure. Upon the twelfth day the inflammatory symptoms had subsided, and not being able to advance the teeth to the proper level by means of the usual appliances, I determined to treat the case by means of a silver suture. The patient having been chloroformed, the central and left lateral incised teeth were extracted. With a shoemaker's awl two holes were drilled, one upon each side of the vertical fracture, as low as possible in the body of the jaw, so as to allow of a good purchase being made upon the fragments when the suture would be introduced. One end of a medium-sized piece of silver wire was passed through one of the openings and carried into the mouth; the other end of the wire was carried through the second opening, so that in front of the jaw there was a loop of the wire, the free ends being in the mouth. By making traction upon the ends of the wire, the fragments came into fair position. Then, by means of the wire twister—used by Baker Brown in cases of ovariectomy—the ends of wire were very firmly twisted; the loop in front of the jaw was brought well home; the fragments then came well into position. The twisted wire, which was now close to the frænum linguæ, was cut off closely, and a piece of lint placed over it to prevent the tongue being irritated. Ten weeks later the wire was removed by cutting it across upon the inner side of the jaw, and making traction with a pair of necrosis forceps. Complete union had taken place, and the teeth occupied their normal position. There was a little thickening in the neighbourhood of the fractures, which would be absorbed in short time.

DR. ROSS congratulated Dr. Browne upon the issue of his case. He said he exhibited great originality in the treatment, showing his readiness to meet troubles as they presented themselves.

¹ [Dublin Journal of Medical Science, 1877, v64, p182.]

Dr. BECK would not use the awl so freely. He recommended the use of a small trochar and canula, such as he used for perforating the lobule of the ear.

Dr. DEMPSEY agreed with Dr. Browne about the great difficulty in maintaining the fragments in position by the old gutta-percha splint. He had treated a case where this was nearly impossible.

Dr. WALES was pleased with the treatment. He said the result commended itself, and he saw no reason why the same course should not be instantly adopted if the older treatment failed in keeping the fragments in position.

Dr. M. MOORE found that the force which caused the fracture in these vases caused more injury to the soft parts, and with him this seemed the difficulty to be contended with. He did not object to any treatment which was sufficient to hold the fragments in position. He had never met with a case in which the milder methods failed him, consequently he had no experience himself in the wire suture. He thought that cases would now and then turn up which no experience would meet, and these must be treated by other methods than those generally laid down.

Dr. Anderson, proposed by Dr. Whitla seconded by Coates, Dr. Speer, proposed by Dr. Esler seconded by Secretary, were to be balloted for next meeting.

Richard Ross

Session 1876

20th February 1877 Seventh Meeting

Present, Drs. Ross, Wheeler, John Browne, Core, McConnell, Strahan, Coates, McKeown, Esler, Whitla, Dempsey, Pirrie

Drs. Speer and Anderson were balloted for and elected.

Dr. Coates exhibited a brain extracted from a patient the recipient of a severe accident.

Dr. McKeown read a paper on a new operation for detachment of the retina.

Paper:¹ DR. M'KEOWN made some observations of a practical character on the surgical treatment of detachment of the retina. He referred to the plans of Bowman and Graefe—viz., the tearing of the retina, so as to open up a communication between the subretinal space and the vitreous humour, and stated that the results were generally so unsatisfactory that he preferred to allow the patients to suffer from the disease, rather than bring surgery into disrepute by practising unsuccessful operations.

For some time he had been thinking that it would be far better to secure, if possible, a permanent opening from the sac beneath the conjunctiva. In that case a retreat of the retina would take place, and improvement of vision result. At last a case, so bad as to justify him in performing an operation, theretofore untried,

and still offering some prospects of success, presented itself.

The following are the particulars:—

Thomas M'Kane, aged seventy, residing near Moneymore, consulted Dr. M'Keown, at the Ulster Eye, Ear, and Throat Hospital, on the 13th October last (1876). He stated that the left eye had been blind for fifteen years. There was a cortical cataract, with total loss of perception of light, from some deep-seated disease. The right eye had been very bad for a year. He could distinguish light from darkness, and could see white objects with bright light shining on them, but could not go about. On ophthalmoscopic examination, a very large detachment of the retina was observed. Only a very small piece of undetached retina could be seen at the upper part, all the rest being either detached or hidden by the detached part, The disc could not be seen. Still the detached retina retained its sensibility, the patient being able quickly and accurately to discern light thrown on the eye from the different direction.

October 14th.—Lifted flap of conjunctiva and exposed sclerotic between internal and inferior rectus, then, with a Graefe's knife, cut out a piece of sclerotic and choroid, about one line in diameter. That was the diameter of the perforation produced; but the diameter of the outer surface of the sclerotic removed, was very much larger. A large quantity of fluid escaped. The conjunctival flap was reapplied and secured in situ by a suture.

15th.—Great improvement. Could count fingers easily in different directions three to four feet, and could discern distant objects. The optic disc could be seen quite well, and the retina for a considerable distance around. The detachment had retreated, and did not seem now to be much elevated from the choroid. In cases of detachment it is generally found that bright illumination is necessary for vision. At dusk or by artificial light he could not see to move about.

Nov, 9th.—Vision has been becoming more misty lately. Exposed the site of the operation; found perforation quite closed; removed another small piece.

January, 1877.—Patient visited Dr. M'Keown this month. He had been able to move about quite well ever since. He has been using strong convex glasses, from which he derives much benefit.

Shortly after this case—viz., in the month of December, Dr. Wecker brought before the profession, in the *Annales d'Oculistique*, a new plan or treatment, which had been used by him, and some seven cases were reported. It consisted in passing a fine gold thread through the sub-retinal space, and securing it there by twisting its two ends outside on the conjunctiva. Dr. M'Keown remarked that if this treatment turned out to be tolerated, it would altogether change many of the prevalent notions about the danger of the contact of foreign bodies with the vascular tunic of the eye. At least, until more evidence were forthcoming, he would

¹ [Dublin Journal of Medical Science. 1877, v64, p441.]

prefer a plan that was not likely to do harm, and to which little objection could be taken. A case soon came before him, in which it came to be a question between the drainage method of Wecker and a subconjunctival drainage through a sclerotic opening. The patient was a gentleman of about seventy-five years old, an invalid for many years, a sufferer from chronic bronchitis and weak heart. His right eye had been hopelessly blind, for a number of years, from detachment of retina by rupture of a vessel; and his left eye, sometime about September, 1876, came also to be affected with a small detachment by serous fluid above. The detachment gradually increased in extent, and ultimately the fluid, in obedience to gravity, descended and detached the retina extensively below, and to the outer and inner side. Dr. M'Keown advised an operation. The patient afterwards consulted Mr. Wilson, who also advised an operation, and spoke of Wecker. It was ultimately arranged that Mr. Wilson and Dr. M'Keown should consult together regarding the method to be employed. On the 31st January, 1877, Dr. M'Keown performed the following operation, assisted by Mr. Wilson:—After exposing the sclerotic between the external and inferior rectus, he thinned the sclerotic over a considerable space; a little flap of the thinned sclerotic was then lifted up and doubled back, and secured by gold-thread suture to the sclerotic. The choroid, of course, was cut, and a large quantity of fluid escaped. In this manner a little trap-door was made into the sub-retinal space. The conjunctiva was replaced and the gold thread hidden from view.

The object in lifting up the flap and tying it back, was to have, as part of the margin of the opening, the inner surface of the sclerotic, which it was surmised might not so readily unite to the rest of the margin, being a sort of serous surface as it were. For sometime the vision was greatly improved, the field of vision being restored; but afterwards matters took a turn for the worse, and the vision relapsed. From the time of the operation the gold thread was not seen, and whether it lost its hold and allowed the little flap to slide back and re-unite, or whether the opening gradually contracted and closed, it was not possible to determine.

DR. M'KEOWN said he felt satisfied that a permanent opening in the sclerotic, beneath the conjunctiva, offered the best hope for these cases, and it was simply a question whether such could, by any means short of the presence of a foreign body, be secured. When he had further experience he would communicate it to the Society.

At the date of publication of this, Dr. M'Keown reports that a short time since he was informed that Thomas M'Kane visited Belfast, in quest of glasses, and that he walked through the streets alone with confidence. As to the other case Mr. Wilson and he had some correspondence regarding further treatment, and it was arranged that the retina should be cut by plunging

Graefe's narrow cataract knife through it. This was done on two occasions, but little change resulted in the vision.

Dr. Esler read a paper upon oakum as an antiseptic dressing.

Paper:¹ MR. PRESIDENT AND GENTLEMEN.—The value of oakum as an antiseptic dressing was first brought under my notice by the late Dr. John M'Crea, who had been for some time using it extensively; and to this, as to all other subjects which he took up, was applying himself assiduously in observing, and noting carefully what he observed, as the result of his experiments. Hence it is more as a tribute to the memory of my late friend that I come before you with these few and imperfect notes, than from any claim I have from my own brief experience, to ask you to take my opinion for anything but what it is worth. At the same time I hope to be able to put before you as many facts as will stimulate an instructive conversation.

Oakum, as you are, no doubt, all aware, is simply tarred rope reduced to its original state of flax or hemp, with the addition of the tar. Any of us who have been a voyage round the world, or even a shorter circuit, may have observed that the idle time of the sailor is often filled up by the occupation of oakum-picking; and in gaols, workhouses, and penitentiaries, it is made an occupation of profit. Old ships' rigging can be bought at about 17s. per cwt., and the oakum, when picked, sells at 22s. per cwt., so that the difference represents labour. The original use to which oakum was put was to caulk the crevices of wooden ships; but modern iron vessels, excepting the decks, do not require, nor will they be satisfied with, such a soft substance to mend their breaches—so that, I suppose, the primary use of oakum was to save life; but, more recently, it has been applied to life-saving in quite a different capacity. During the American war, carded oakum was employed extensively in the dressing of wounds; and, subsequent to that time, the surgeons to the Children's Hospital in Great Ormond-street, London, introduced it to this country.

Early in the year 1870, The Lancet drew the attention of the profession to it, as used by Mr. Pollock, at the St. George's Hospital, and gave it as their opinion that it would supersede other methods, and one reason was its low price, quoting it, as prepared by Bell of Oxford-street, at 1s. per lb., but you will observe that the price which I have paid for it is a little more than 2¼d. per lb. About the year 1870, Professor Lister put the antiseptic qualities of oakum to the test, and found it to answer his expectations; his observations are recorded in The British Medical Journal of January of the following year. Trélat, a French surgeon, also used it some five or six years ago, and I suppose that, at the present time, it is to be found in the wards of most of the hospitals of

¹ [Dublin Journal of Medical Science. 1877, v64, p324.]

this country; but it is because I do not think that its true value has been ascertained, that I wish to press its use upon your attention. Why it is in use in our hospitals, or by whom it was introduced, perhaps few of us have paused to inquire; but it may be enough for us to know that, having it there, it is a suitable agent, in many respects, with which to surround suppurating wounds. And we hope to be able to show that, as an antiseptic agent, it is superior to any other ready-made substance we possess.

My observations have been made first, in the Union Infirmary, and subsequently, but more minutely, in the Ulster Hospital for Children, and they have been in the following class of cases:—Amputations, abscesses, ulcers, cutaneous erysipelas, phlegmonous erysipelas, and burns. The number of cases of the first class in which I have used this dressing have been in two major and several minor amputations. Either of two methods may be adopted. In the first, the dressing is made as simple as possible. A single strip of lint soaked in carbolic or spirit lotion, applied next the wound, with a roll or two of bandage to hold it in position, and the stump then surrounded with oakum and another bandage if necessary, or you may apply the oakum next the wound, and this method is less objectionable than would at first sight appear; and, for reasons to which I shall presently allude, the flax may be much preferable to cotton in contact with a granulating surface. The advantage of this dressing is, that for stumps it is simple of application, it makes a soft pad on which to rest, and, what is of the greatest importance in the wards of an hospital, it effectually keeps down any offensive odour—and more, its effect seems to be to destroy the putridity of the discharge, while the pleasant tarry smell is strongly suggestive of the sea, of ships, and of fresh air. In most of the cases in which I have seen it applied, healing has taken place by the first intention, and this is, no doubt, partly accounted for by the freedom with which the serum is discharged from the wound, and by the prevention of ingress to any substance which would favour decomposition.

In a Chopart's amputation, in the Children's Hospital at present, you may see the result of this dressing. I am applying it next the wound; it has kept perfectly sweet. And this I attribute to the antiseptic properties of the oakum in which the stump was enveloped.

In Abscesses.—I have opened some dozens of abscesses where the only subsequent treatment was a pad of oakum bandaged over the part; and, in every case where there was not diseased bone underneath, the result was more satisfactory than I have ever seen from any other treatment. I will instance one case, that of a labourer, aged about fifty:—The abscess was gluteal, and had grown to almost the size of his head; the skin and muscles were enormously distended. So tedious did I expect the healing that I thought of introducing a drainage tube or plug, but having faith in oakum, I

applied a good large pad over the part after evacuating the contents, directed the man to lie on it, so that any discharge might drain into the oakum. The shrunken skin and relaxed muscle, in a few days, seemed to fit into their places, the opening healed without a blush of inflammation, and in a week the man was in his usual health. In some cases it is desirable to poultice for some time before using the knife, and we all know how troublesome it is to continue this for any length with linseed meal, and many surgeons have a great dislike to these oily applications. Liston said, nearly forty years ago, that "hot dressings, filthy unguents, greasy poultices, stimulating plasters, and complicated bandages must give place, very soon, to the elegant substitute for a poultice," referring to isinglass plaster, "and to careful position of the injured part;" and added that it was so long since he used these filthy compounds that his nurses had forgotten how to make them. Now in oakum we have the material for an antiseptic poultice, in abscesses or inflammatory attacks, by simply dipping it in hot water and covering it with waterproof tissue.

In speaking of Erysipelas, I need not refer to the many specifics which, from time to time, are recommended and vaunted, nor to the difficulty experienced sometimes in controlling the disease, nor will I allude to the constitutional treatment which should not, in any case, be neglected, but simply to the local application of oakum as a remedy, and I will instance a case or two, in both the cutaneous and phlegmonous stages, in illustration of what I have observed in treatment with this material. The first happened in the Accident Ward at the Union Infirmary, where a strong man, who had been recently admitted, presented one morning the characteristic appearance of the erysipelatous inflammation; the left side of his face, but especially his eye, was most effectually disfigured. I was accompanied by the house surgeon, to whom I said, "What would you do for this man?" His reply was, "Apply a pad of oakum." So I said, "A pad of oakum let it be." The following day there was scarcely a trace of the inflammatory action present, the swelling had subsided, and there was no return; the application was kept on, however, for several days.

A strumous boy had a true erysipelatous blush on the wrist of the left arm. Next day it had extended as far as the insertion of the deltoid; the limb was surrounded by oakum; the inflammation was arrested at the spot then affected; the arm got well; metastasis followed, however, and the face was attacked a couple of days subsequently. The same application brought about the same result, and I find that Dr. M'Connell is so well pleased with the line of treatment that, when I visited the Infirmary a few days ago, he had several erysipelatous patients encased in oakum. So much for the cutaneous variety. And in the deeper and more serious stage of the same disease—viz., the cellululo-cutaneous, where abscesses have formed, or sloughing is taking place, I

am of opinion that oakum is simply invaluable.

The first case, in illustration, which I will mention, was that of an elderly man whose right leg was very extensively involved. The first abscess formed over the fibula, the next above the knee, and another in the vicinity of the groin. I used the knife freely; and, as I had before my mind's eye several cases of poulticing and extensive sloughing, I decided on enveloping the limb in oakum only. No other application of any kind was employed; the patient was anæmic, and the prognosis of the gravest kind. The effect of the dressing was to most thoroughly keep down any smell. Almost immediately healthy action set up, not an unfavourable symptom was present by the end of a week, and the recovery was rapid and satisfactory.

The second case was that of a female lunatic; the part affected was the left leg; the course pursued was the same; and, as far as the leg was concerned, the healing process went on, but bed-sores formed, and the drain on the system was so great that death resulted; but the comfort, the simplicity of the application, and the comparative absence of putrid odours, during a long illness, were results not to be lightly valued.

Oakum in Treatment of Burns.—I need not say a word, by way of introduction, as to the offensive nature of the discharge from burns and scalds, and any means of controlling or lessening this will be hailed by the surgeon and by his staff of dressers with pleasure. Now, I venture to state that one of the best agents we possess for this purpose is oakum; its value as an antiseptic is even more marked in this class of cases than in the former. And while I would rather not have a burnt case in an accident ward, yet, were I obliged to do so, I would simply surround the patient with plenty of oakum, make the dressings so thin and simple that the discharge would flow freely into the tarry mass; and by renewing this sufficiently often, the matter will be prevented emitting that characteristic odour of burns which is so overpowering, and the labour of the dresser will be much lightened.

I have thus treated about a dozen cases of burns, some of them very extensive, and in all the smell was so thoroughly kept under that the patients were not more to be dreaded in a ward than any other surgical case with an extensively abraded surface. Nor need there be any hesitation about applying it next the burn without any other substance intervening. And it does not seem to be so difficult to get it detached as lint; but surgeons' lint, in common use, which should be made of flax, is composed altogether of cotton. You know there is a popular notion that cotton is an exceedingly bad application to sores, that it causes great irritation, and that linen is preferable, and these popular notions are invariably based on correct observations. We may pause here for a moment to inquire is there any cause for this. When we place a fibre of linen and one of cotton under the microscope, we might infer that the cot-

ton would be the less irritating of the two, as its fibres are not so sharp or well defined. Indeed the cotton, although flat, has a perceptible thickness at the edges, is rounded, and somewhat like a thin tube flattened; the flax is not so tubular, not so well defined or rounded, and is sharper; but if, after examination in the dry state, we apply moisture, the cotton fibre is found to twist in a spiral manner; and, perhaps, it is this hydroscopic power of twisting, when moistened, that gives cotton its irritating qualities, and the absence of this quality in the flax which makes it strip off granulating surfaces so easily.

To briefly sum up. The conclusions at which I have arrived, regarding oakum as a dressing, are that:—It is cheap; it is clean; it is easily applied; it is equal to any, and in many respects superior to most other dressings of the same class; and that it is antiseptic. I have not tried to demonstrate by experiment, apart from clinical observations, this last quality, but I intend to do so. And only that it is a wrong method to enter upon an investigation with a preconceived notion, I would state my conviction that it will be found to present a barrier to the ingress of spores or sporules, or whatever germ life infests the atmosphere, and which are such a bugbear to a large school of operating surgeons. Should this opinion prove to be correct, it will be just simplifying Lister's antiseptic method, the principle being exactly the same, as tar and carbolic acid stand side by side as therapeutic agents.

Tar is very complex in its composition; it is an altered resin and an empyreumatic oil, in which the following substances are found:—Creasote, paraffin, picamar, and eupion. It is obtained by the destructive distillation of the *pinus sylvestris*, and at gas works, which is a huge destructive process of the old pine forests, as they appear to us in the form of coal beds.

As a therapeutic agent, tar is used principally in chronic skin diseases; its influence on mucous membranes is sometimes well marked; and, in the form of inhalation, the oil of silver pine often gives satisfactory results in chronic bronchial affections.

Tar water long enjoyed a reputation as a specific in numerous diseases: it is made by shaking up one part of tar with, four parts of water. The celebrated Bishop Berkeley entertained the notion that, tar water was a certain remedy for every form of disease. And as the old philosophers cried aloud from the housetops to their fellow-citizens—"Educate your children," so the bishop said that if he had a situation high enough, and a voice loud enough, he would cry to ail the valetudinarians upon earth—"Drink tar water." I would not be quite so enthusiastic regarding this tarry preparation, oakum; but, by this paper, my appeal to all who are practising surgery is—"Try oakum dressing."

Had we to manufacture our dressings from the *pix liquida*, it would be both troublesome and expensive, but the sailor has done this for us with another object

in view. And after the rigging has served its purpose on board, and carried the sails which wafted the A 1 at Lloyd's under a tropical sun to many a foreign port, it is sent on shore for our convicts and paupers to prepare, for a short but useful course of service, in the wards of our hospitals. We intend to try it, pay for it, and use it, until we find something to supersede it.

Dr. J. W. Browne congratulated Dr. Esler upon his paper, especially referring to the microscopic features treated in it. He had been using oakum since 1875. He had seen his friend, Dr. Fagan, use it in 1871, and was much pleased with it. Since then he used it for everything himself—for amputations, burns, &c.

He believed it was first introduced by Sayer; its great beauty was in its elastic and antiseptic properties. In the treatment of burns he did not apply it immediately to the skin, but used a fold of lint saturated, with a solution of sulphate of iron (5 grains to the ounce).

DR. DEMPSEY saw a Dublin surgeon use oakum five years ago for all his amputations, which seemed to him to modify, repair, and promote union in a satisfactory manner. He used it himself after the opening of deep abscesses, and was much pleased with it.

DR. COATES saw it used in hospital extensively, but chiefly as a deodoriser, but he thought it had several objectionable qualities; as a dressing he did not think it suitable. In the hospital, sometimes, burns were dressed under the spray; this he thought advisable, and he recommended the practice of putting carbolic acid into the dressing of Carron oil.

DR. STRACHAN stated he had, in the Union Hospital, frequently seen Dr. M'Crea use the oakum as an application to ulcers with very good success.

Dr. M'CONNELL said he was at present using the oakum as an application to indolent ulcers, and he found, in some instances, that it changed their action in twenty-four hours.

DR. M'KEOWN thought, from listening to the paper, that the oakum could not possibly be an irritant. Any dry clean substance was preferable to a poultice. As to the question of germs, this, he thought, had to be settled. No doubt good results followed the treatment of those who advocated antiseptic surgery; this, he thought, resulted from the fact that all who had germs on the brain took a great amount of care in dressing their cases. Speaking of ophthalmic surgery, he said here Lister's spray could not be used. Ophthalmic surgeons never dream of germs. Of eye operations lasting ten or twenty minutes, take one hundred cases, and at the very utmost five will show any traces of suppuration. He thought quite too much had been made out of this germ question, but in the end good would result in making men more careful of their dressings. He referred to Hebra's views on erysipelas. He thought that, as regarded the application to ulcers, the pressure was the main point, not the antiseptic quality of the

oakum.

DR. WHEELER, in thanking Dr. Esler for his paper, said he believed that oakum would supplant cotton-wool; he had long given it up for tow, the wool makes such a hard doughy pad, but oakum was decidedly better than either. He never used cotton lint when he could get old linen.

The election of Honorary Members was postponed till next meeting.

Thomas K. Wheeler

Session 1876–77.

20th March 1877 Eighth Meeting

Present, Dr. Wheeler in the chair, John Moore, James Moore, Dempsey, Fagan, Esler, Beck, Anderson, McIvor, Harkin, O'Malley, and several students. J. W. Browne.

Dr. Fagan read a paper upon excision of the knee joint and exhibited three patients upon whom he had performed the operation.

Paper:¹ MR. PRESIDENT,—I have shown you this evening three children on whom I performed excision of the knee-joint. I consider the cases interesting, as they are, so far as I know, the only ones of the kind that have been brought under the notice of the members of the Ulster Medical Society.

I also consider it to be the duty of every surgeon, no matter how limited his experience of the operation may be, to record the result of his observations, in the hope that, by thus increasing the store of facts bearing on the subject, more definite rules than those already existing may be laid down for the guidance of surgeons on this much-vexed question.

Mr. MacCormac, of St. Thomas's, a former member of this Society, in a paper on the "Relative Merits of Excision and Amputation" (1868), says:—"There is almost no established surgical procedure regarding which such wide differences of opinion exist, or about which controversy has more hotly raged."

The first case I will record is the one I last operated on, and although on it I expended most care in carrying out all the details of the operation and after-treatment, it is the least successful of the three.

In two of the cases the operation has been done a year and a half, in the third a year. Observations made after the lapse of so much time are of very great interest regarding one feature of the subject in the case of children—for it is urged by some as a powerful argument against the operation that after it there is arrest of growth in the limb. You will have observed that such is not the fact in the cases I have just now shown you.

CASE I.—Alexander Cardwell, aged five years, was admitted to the Children's Hospital, under my care, in the month of October, 1875. About four months previ-

ously the mother noticed him limping in the mornings; about a month afterwards she observed the knee somewhat enlarged. She applied some simple remedies and paid no further heed to it for some weeks more, when she was advised to take the boy to the hospital. The only cause she could assign for his state was a fall on a heap of bricks, and she supposed his knee came against the corner of one of them.

He was subjected to the stereotyped treatment followed in the subacute or chronic inflammation of joints. The joint was carefully strapped with soap-plaster and securely placed on a M'Entyre's splint. He remained under treatment in hospital for upwards of two months, when the mother had him removed. He was re-admitted, under my care, on the 14th March, 1876, when he presented the following symptoms:—

The leg was very much flexed and wasted, the joint enlarged and globular, the ends of both femur and tibia enlarged and very painful on pressure. He was losing flesh rapidly, suffered from irritative fever, sleeplessness, loss of appetite, and had painful startings of the limb at night. His general condition improved after his admission, but that of the knee was no better. Fig. 1, Case I., is a very faithful representation of his case a few days before operation.

On the 11th of April I removed the joint in the following manner:—The child being fully under the influence of ether, and Esmarch's elastic band applied, I began my incision at the back of one condyle, and bringing it just under the patella, terminated it at the back of the other condyle; I reflected the flap with the patella, and, having seized the latter with lion forceps, carefully dissected it out. I next freed the lateral ligaments, flexed the leg on the thigh, and pushed the tibia forcibly forwards; by this manoeuvre the crucial ligaments were put well on the stretch—then, by directing the edge of my knife in a line with the tibia, I cut on its articular surface behind the spine, and in this manner severed them without in any way endangering the vessels behind.

I then pushed the end of the femur forwards and

cleared it of surrounding tissue, as far as the point at which I was about to apply the saw. With a Butcher's saw I removed the lower end of the femur, in a horizontal line, from a point about a quarter of an inch below the upper edge of the trochlear surface in a direction from before backwards. I next removed a thin slice from the tibia, including little more than the articular surface, sawing from behind forwards; then, with a curved scissors and forceps, I removed all the pulpy and fatty tissue exposed in the wound. The elastic cord, was next removed; I twisted a few arteries, which spouted. There was pretty free oozing from a number of articular twigs which I could not seize with the forceps, as they were buried in the adjacent fibrous tissue; there was also considerable oozing from different points of the sawn surface of the bone. To all these points I applied the actual cautery, and by this means completely arrested the hæmorrhage; I then freely swabbed the parts with a solution of chloride of zinc (gr. xv. to ℥i.), and placed two pieces of carbolised tow in the back of the wound with the ends hanging out at either angle, I brought the bones into apposition without any difficulty, and closed the skin wound with five points of carbolised catgut suture. The limb was then washed, dried, and dusted over with powdered oxide of zinc, and after a flannel bandage had been applied from the toes to the groin, it was placed on a splint that was already prepared for it.

Dr. P. H. Watson's plaster-splint was the one used, and I consider it the most suitable of any yet devised for the purpose. When the plaster had set I removed the child to a bed prepared for him, and ordered a little hot brandy and water, which I find to be an exceedingly good sedative for children after operations.

After closing the wound I placed an ice-bag over it, and had cold sponges applied at each angle to absorb any discharge of blood or serum that might flow from it. I left it exposed in this way for five hours, when there was scarcely any discharge. I then carefully packed all round the wound with carbolised tow, put a pad of the same material over the joint, and a bandage over all, in this way rendering the parts perfectly secure. The limb was placed on a pillow between sand bags.

April 12th.—Pulse 136; temp. 101; had a restless night; vomited two or three times; bowels moved twice. Slung the limb to-day from a Salter's swing.

13th.—Pulse 130; temp. 100.3; slept pretty well; takes plenty of milk; looks bright and happy.

14th.—Pulse 120; temp. 100; slept well; takes his food well.

15th.—Pulse 120; temp. 100.2; slept well; eats well and looks well.

16th.—Dressed the limb to-day (the fifth after operation) for the first time. There is scarcely any swelling, no appearance of inflammation, and only a slight serous discharge into the tow. The wound appears uniting by the first intention. I removed the tents from

the wound, and some of the tow in contact with it that was soiled by the discharge. I introduced fresh tents, and padded round the joint as before. The boy was sitting up in bed two days after the operation, and from that time complained of no pain whatever.

30th.—Since last notice the limb has been dressed every second or third day. The wound is quite healed, his health good, and he has suffered, no pain.

May 26th.—I removed the splint to-day. There was some excoriation of the skin over heel. The limb was in good position, but as the bones did not appear to be quite firmly united, I put it up again in the same splint.

June 17th.—He is very much improved in every way since last notice. He can raise the foot from the bed with ease. The limb was carefully put on a back splint, and he was taken to the country.

July 22nd.—He was again admitted into hospital. The cicatrix has an unhealthy appearance; a sinus leads from the inner side of it for about an inch deeply under the skin, and the outer end of it for an inch has ulcerated. He is not able to raise the limb from the bed. There is no mobility, but there is evidently a retrograde condition of the connecting medium of the bones.

The treatment I employed was securing the limb firmly on a splint, applying some stimulating dressing to the wound, and giving him iron and cod-liver oil with suitable nutritious diet.

August 10th.—Was taken home to-day very much improved in health. The ulcers were not yet healed; splint still kept on limb.

September 8th.—Was again admitted into hospital. He is still improving in his health. The same treatment carried out. About a week after his last admission the cicatrix, was completely healed, and, for the first time, presented a truly healthy appearance, and caused him no pain when pressed on. He began to walk, about the ward, at first with the aid of the beds, but after a little was quite independent of any support.

On the 12th October, just six months after the operation, he left the hospital quite restored to health, and with a very useful limb. The amount of shortening, on the most careful measurement, was about half an inch; and the angle at the joint just sufficient to render progression most easy.

Six months ago he left hospital a good example of a successful case of excision, as is fairly represented in Fig. 2, Case I., of the accompanying Plate.

Neglect of both his limb and his constitution has left him in the condition you have just seen him. The angle has approached more a right angle, and, as he can only approach the toes to the ground, progression is very much interfered with.

CASE II.—Ellen Templeton, aged six years, was admitted, under my care, on the 1st September, 1875.

About a year and a half previously she first complained of pain in the knee, for which she was treated. Some time after she got a fall on the injured knee, mak-

ing matters worse. About eight months before her admission to hospital the knee began to contract; she complained of painful startings of the joint occasionally through the day and every night when going to sleep; and for the past three or four months could not bear the weight of the body on the affected limb. Latterly her health began to break down; she had enlarged glands under the jaws, suffered from otorrhœa, and had an unhealthy strumous appearance. The joint was enlarged and globular, and very painful on pressure, especially on the outer side of the patella and over the ends of femur and tibia.

The child's general condition was much improved by her stay in hospital before the operation.

On the 28th of September I excised the joint in the manner described in the last case, except that I did not use Esmarch's band, nor apply the cautery so freely.

There was a considerable loss of blood during the operation, and about four hours after it I was sent for, as she was in a very restless and weak condition. The sheet was soiled with blood, which I found was coming out between the upper end of the splint and the buttock.

I removed the bandage and tow-dressing from the wound, and found slight oozing from its internal angle; as the quantity coming away was slight, I did not further interfere, but left the part exposed, applied an ice-bag, ordered a sedative draught, and a little iced milk and brandy for drink.

29th.—She slept a little through the night. There was no further bleeding. Pulse 156; temp. 99.6; she looks brighter. I stopped cold application, and applied a pad of carbolised tow and a bandage.

30th.—Pulse 154; temp. 100; slept pretty well; vomited a couple of times; started occasionally in her sleep, and complained of pain in the knee.

October 1st.—Pulse 146; temp. 99.4; slept well; had her bowels moved; took an egg for breakfast, and had some milk and brandy through the night. I looked at the wound to-day, and found it so healthy, and with scarcely any discharge from it, that I did not consider it necessary to remove the dressing. She complained of an itching sensation in the groin under the splint; this, I believe, was due to the irritation caused by the hæmorrhage and cold applications after the operation.

3rd.—Pulse 138; temp. 100; is much improved in every way. I dressed the wound to-day; it was nearly healed up by the first intention, except at angles where the tents were kept in for drainage. There was no swelling or inflammation about it.

From this date the case progressed favourably. The wound after a short time was entirely healed; and on the 29th November—just two months after the operation—I removed the splint.

There was slight abrasion of skin over dorsum of foot and back of thigh, which healed in a few days.

Notwithstanding the fact that the splint and dressings were saturated with blood, and the cold applica-

tions used to check the hæmorrhage, no uneasiness followed; it never interfered with the satisfactory progress of the case.

The union seemed to be perfect. I put the limb again on a splint, and in about a fortnight allowed her to move about on crutches. She left the hospital about four months after the operation.

A slight abscess formed over the head of the tibia, but after being opened gave no further trouble.

It is now a year and a-half since the operation was performed. The limb is about half an inch shorter than its fellow. She has been attending school and enjoying herself at her games like other children. Her general health has been the best, and the limp in her gait is the only apparent evidence of her having undergone so serious an operation as excision of the knee-joint.

CASE III.—Ellen Wilson, aged nine years, was received into the Belfast Hospital for Sick Children, in August, 1875, and placed under my care.

Her mother gave me the following history:—Three years previously she was thrown over a form at school and got her knee hurt; it was painful and lamed her for a considerable time. She used a liniment, but was not particular in keeping the limb at rest.

About a year and a-half ago she was in the habit of skipping a great deal, and again complained of pain in the injured knee. Whatever treatment was employed gave her temporary relief.

Nine months before I saw her the limb began to contract. She was placed under a doctor's care for some time, but as she was gradually getting worse, the mother had her removed to hospital.

The condition of her joint was the same as in the first case, but her constitution was much healthier.

On the 15th September I removed the joint in the manner already described; no bad symptoms occurred during her progress towards recovery. I removed the splint on the 4th November. Union was perfect. Three weeks after this I allowed her to get about on crutches, and she left the hospital, able to walk without any support, between three and four months after the operation.

It is now a year and a-half since the operation. There is about half an inch shortening. She is the type of a healthy child, and can walk any reasonable distance without being fatigued.

The pathological condition of the joints was what is usually observed as the result of chronic inflammation.

The tissues around the articulation had degenerated and were infiltrated with gelatinous matter, inside the joint the synovial membrane was in some parts thickened and pulpy, in other parts highly vascular, and extended in fringes over the cartilages. The cartilages in most parts had lost their polish, and showed here and there pinhole depressions.

In Cases I. and II. the cartilages suffered most, being completely absorbed at one or two points, and at others

very much thinned. In Case II. there was a small circumscribed abscess in the joint, as well as considerable disease in the end of the femur. After removing the recognised extent (by the saw) I had to use the gouge to remove two carious spots—one in the centre, the other at the side extending up to the epiphysis.

In all the cases the side of the cartilage resting on the bone had depressions over it, into which projected little masses of granulations. The articular lamella was highly vascular, and, in parts, softened, and was easily removed from the super-imposed cartilage. The ligaments in some places were degenerating, and, in Case II., the crucial were partly destroyed.

Before making any remarks on the subject of excision, I will give the history of a case of chronic knee-joint disease treated by the expectant method. It is a typical one of a very large class, and will serve to illustrate my remarks on the subject further on:—

CASE IV.—Thomas Shannon, twelve years of age, was admitted into hospital three years ago, suffering from disease in knee-joint. About a year previous to his admission he fell down the school stairs and hurt his knee. No special care was bestowed on it; the mother thinking he was affected with “growing pains.” However, as the pains and swelling of the joint increased, and the limb began to contract, she took him to hospital.

After two months' stay his general condition was very much improved, but the state of the joint was much the same. At this period I proposed excision, but the parents would not consent to it.

Fig. 1, Case IV., conveys a pretty accurate notion of his state at that period.

He was removed to the Throne Hospital, and remained there for nearly six months.

The greatest care was bestowed on the treatment of the joint affection, while he was exceptionally well-circumstanced for the improvement of his general health. Notwithstanding, the disease slowly progressed, the joint became more swollen and tender; the painful startings more frequent and severe. A small abscess formed just under the knee, but did not communicate with the joint. After he had spent a year in hospital the mother took him home, when he got rapidly worse. Suppuration of the joint took place, sinuses formed around it, the leg became contracted on the thigh, his constitution was completely worn down by suppurating fever, and a year after leaving hospital he was re-admitted to have the limb amputated. Fig. 2, Case IV., is a good representation of his state at this time.

After he was a few days in hospital some ignorant friends prevailed on the mother to prevent the limb being removed. Since that time he has been dragging out a miserable and painful existence.

The probabilities are that he will very soon die from the effects of the disease, or, if he should survive, it will be with a shattered constitution and crippled for life.

You will have observed, Mr. President, from my report, that in each case the disease originated in the receipt of some slight injury, and that the destructive changes commenced in the articular ends of the bones, the inter-articular tissues becoming secondarily engaged. Also, that the subjects of my operations were under nine years of age, a period when any interference with the growth of the bone would be detrimental to the use of the limb in after-life.

In treating the subject of excision, I will direct myself more especially to the consideration of these points, as well as to some of the conditions that should influence the surgeon in the selection of his cases for this operation.

Excision of the knee-joint is not a new operation. Mr. Filkin, of Northwich, performed it as far back as the year 1762; and although practised occasionally by some of the more advanced surgeons of the French school, it was only lately, through the labours of Sir William Ferriusson, that it became an established surgical procedure in this country.

Like every other novelty in the domain of medicine, as well as surgery, excision of the knee became the fashion, and its indiscriminate application by some surgeons to all kinds of knee-joint affections brought the operation into disrepute. This developed another party—the anti-excisionists—who discountenanced the operation altogether, and a hot contest was carried on for some time between the advocates on both sides.

At the present time excision of the knee as an operation is looked upon by surgeons as a justifiable procedure in conservative surgery.

To my mind, successful results depend mainly on the careful selection of cases; the important point the surgeon has to decide on being, what is and what is not a suitable case for operation.

The surgeon who views his cases with a mind free from prejudice will meet amongst them some that are suitable for the expectant treatment, others for excision, and others for amputation; and in recommending each of these methods as he sees fit, he will best serve his patient's welfare, and will not bring any special line of treatment into disrepute.

Mr. Spence, in the last edition of his *Surgery*, when comparing the results of his first operations with those lately performed by him, says:—"This favourable change in the results of my excisions of the knee, is, I believe, greatly due to the experience of former years having led me to exercise great care in selecting proper cases for the operation, and in eliminating those in which the nature of the disease or its complications, the age, or debilitated state of the patient, seemed unfavourable for such an operation."

In making a selection, three points have to be taken into consideration—viz., the state of the constitution, the condition of the joint, and the age of the patient. A careful examination of all the organs should be made,

and the surgeon influenced by the result.

The more healthy the constitution, the more favourable is the case for the operation.

Regarding the condition of the joint, it is found that the operation is most fatal in cases of injury and acute disease.

In the treatment of the subacute or chronic disease as ordinarily met with, the nice point for the surgeon to decide on is—in which stage of the disease, and under what circumstances, should he adopt the expectant method, in which recommend excision or amputation. We may here dispose of the two extremes of this condition. In the initiatory stage the expectant is the best and only justifiable means of treatment; while in the advanced condition of the disease, where the bones are involved beyond the epiphysis, the soft parts degenerated and riddled with sinuses, and the constitution depraved, amputation is the only mode of treatment that ought to be entertained.

The cases that require most careful consideration before recommending any particular line of treatment, are those holding a middle position, of which there are two kinds. One, generally known under the name of "white swelling," has been fully described by Sir B. Brodie. In this condition the disease begins in the synovial membrane, is usually idiopathic, progresses silently; in many cases there is an entire absence of painful symptoms, and the constitution is generally depraved. I have frequently met with such, but have no experience of the treatment by operative interference.

Mr. Barwell recommends a stimulating treatment—such as friction, passive motion, and iodine injections. I am disposed to agree with Mr. Holmes in advocating excision in this class of cases, where the bones are not very extensively involved, and the constitution fairly good.

The other condition of joint belongs to a class of which the cases I have shown you this evening were fair examples when first brought under my notice, the symptoms and pathological condition being somewhat alike in all of them.

The disease, originating in some trivial injury, manifested itself as an articular osteitis—the cartilages, synovial membrane, and ligaments being secondarily involved.

I may here remark that if more care was bestowed on the simple joint-injuries occurring to children—by twists and blows, falls down stairs, off chairs and tables—we would witness fewer painful cases of disorganised knee-joint than present themselves so frequently at our hospitals.

The course I pursue in cases similar in their nature to the ones I have shown you, is as follows:—

If the symptoms are not very urgent and point to the disease as limited to the articular ends of the bones, or involving but slightly the other joint structures, I adopt in every case the expectant method; if, after a

fair trial of this, the condition is much the same, or but slightly improved, I am mainly influenced in the further treatment of the case by the social condition of the patient.

Amongst the well-to-do classes the patient has all the advantages of suitable appliances, is placed under skilled supervision, and, most important of all, the courses of treatment can be continuously carried out under the most favourable hygienic conditions.

Contrast this with the case of the child of the poor person similarly affected. If treated in hospital he may be discharged after a lengthened stay very much improved, or, to all appearance, cured, but want of care on the part of ignorant parents, a too-early return to his employment or his active games, together with want of proper nourishment for his originally feeble constitution—all tend to light up again the smouldering embers of the disease, and he returns to hospital a second time in a worse condition than the first.

While in the one case there is a fair prospect of a cure by natural processes after a lengthened period of treatment, in the other such prospect is but very slight, and, I believe, that for it excision of the joint before the disease has advanced too far, and while the constitution keeps good, is the best method of treatment to adopt.

No matter how favourable the surroundings, if after a fair trial of the expectant method the symptoms increase in severity, and the condition of the patient be gradually becoming worse, both as regards the local affection and the general constitution, excision of the joint is, I believe, the best and only line of treatment that should be recommended.

The train of symptoms and ultimate result are well exemplified in Case IV., which is a good type of its class. In it the expectant treatment was rigidly carried out for a considerable time. Excision was proposed at a suitable period, and rejected; amputation at a later period was proposed, and rejected; and, from the mother's statement a few days back, I believe the boy to be in a dying condition.

Of the many objections that are urged against the operation, I will now deal with one that is considered a strong one in the case of children—viz., that there is an arrest of growth in the limb.

Dr. Watson, an authority on the subject, says:—"In children I have hitherto regarded amputation as a preferable operative procedure, and shall continue to do so until I have had satisfactory evidence that the limb grows, or that the short and shrunken limb is capable, with the aid of a wooden pin, to support the weight of an adult body more satisfactorily than a thigh stump and a wooden leg."

You have, in the cases exhibited here this evening, evidence that the operation can be performed without interfering with the growth of the limb. Two of the cases are good examples of the splendid results that

may be obtained by the operation, and their shapely and useful limbs would form a pleasing contrast with the results of the expectant treatment, or amputation, as exemplified by a wooden leg, or a crippled limb and a shattered constitution.

In my description of the operation you will have noticed that I was careful in making the section of bone wide of the epiphyseal cartilages in both femur and tibia; by so doing I avoided interference with the main source of the growth in the bones, while I effectually removed the diseased structures.

In Case I. the ultimate result is not so satisfactory as I anticipated; the usefulness of the limb will be interfered with owing to the bad angle at which it is placed.

This condition I do not attribute to any fault in the operation. You will remember that his convalescence was rather tedious, and that a considerable time after the wound was healed and the bones firmly united, the cicatrix ulcerated, and the bond of union between the bones began to degenerate.

Under general tonic treatment and rest he improved, and left the hospital, after a lengthened stay, in quite as good a condition as the other two cases. When leaving I put the limb up in a Bavarian splint, and cautioned the mother not to let him put his foot to the ground, but to get about on crutches. The child was neglected and let do pretty much as he liked. Through want of care and nourishment the constitution became impaired, and the same degenerating changes began to take place in the bond of union between the bones, while the weight of the body forced the limb into the angle at which it is now set. This degenerating change in the new connecting medium I look on as analogous to rickets, and should be treated in a similar manner to that affection.

As regards special treatment in this case all, I think, that can be done for him at the present time is to try and prevent his condition getting worse, and then, after the limb has attained its full growth, the propriety of straightening it by taking out a wedge-shaped piece of bone may be entertained.

His case is very instructive, as showing the necessity there is for the greatest care being bestowed on every case, not alone as regards the immediate after-treatment, but until such time as that there can be no doubt about the healthy character of the connecting medium.

I feel that this paper has reached to too great a length for one evening, notwithstanding I have passed over a host of important points in connexion with the operation. There is one other point I will notice before concluding—viz., the comparative mortality of excision and amputation.

A very great deal has been written on this aspect of the subject, and elaborate statistics compiled to suit the advocates of either operation; and after puzzling oneself with piles of evidence for and against, it is refresh-

ing to light on the following expression of opinion of so able a surgeon as Sir W. Fergusson:—

“Allowing, however, that excision was somewhat more fatal, supposing that one life was lost for every six legs saved, was not the gain worth the risk?”

It was partly a question for the patient. Instrument-makers had certainly contrived some most ingenious and elegant limbs of cork, willow, and ash; but people, as a rule, preferred the old-fashioned flesh and blood article, and were willing to run some risk in order to retain it.”

Dr. JAMES MOORE had seen this operation performed by Sir William Fergusson, Syme, Liston, and in the Belfast Royal Hospital; but the cases were principally adults. As a rule, for this operation you have scrofulous subjects to deal with; but, in children, this rule does not hold good for joint diseases generally. He believed, in properly selected cases, it is a good operation, but, on the whole, he does not recommend it.

DR. DEMPSEY, while speaking favourably of the operation, and thinking well of these particular cases, said he believed that the great care and trouble in looking after and attending to the patients, was an objection to the operation.

DR. JOHN MOORE said that it would be an advantage, in judging of the value of an operation, to see the cases at a later period, as the growth of the limb cannot be judged fairly of for some time. He said he was struck by the number of maimed children turned out of school. After a careful reflection on the numerous cases of other surgeons, which he had watched, he came, to the conclusion that it is only in children and young adults that the operation is at all admissible. On the whole he did not look upon the operation with a favourable eye. He did not agree with Sir William Fergusson, that six limbs were worth one life. He preferred life to limbs, and thought that with their admirable anatomical mechanic's (Adam Sloan's) assistance, they could turn out better cases by amputation than by excision. He considered that we were on the border-land of a change in knee-joint treatment, and that incision would take the place of excision. In many cases, he thought, a good free incision productive of the highest good; it relieved tension and evacuated matter, the presence of which was fatal to union or repair.

DR. F. BECK had not been struck favourably with the operation hitherto, but would be inclined, from Dr. Fagan's cases, to adopt the method of excision, but only in children or young adults; as to him, in adults, it still seemed unjustifiable.

DR. ANDERSON referred to the success of Mr. Croft, and stated that he had heard him say that old excisions were turning up now and then, and gave considerable trouble in after-operations.

DR. HARKIN thought excision a better operation than amputation, and that the case of No. 1 was surgically successful; had the child been under happier auspices,

the result would have been equal to the others. He did not think the limb would become shortened when the epiphyses were left intact, and the arterial supply not interfered with. He supposed Liston's method had been adopted.

DR. WHEELER said in all cases he thought conservative surgery should be tried first, and then excision, and, failing this, amputation should be performed. He thought it of great importance that the patient should be left as long as possible in the convalescent home. As regarded statistics, he placed no reliance in them, and his experience of surgeons amounted to this, speaking generally, that the man who advocated excision operated at an earlier date than the amputator—so early, it was anxious to have a good list of successes, as to sacrifice life in cases where conservative surgery would have turned out a sound limb; while, on the other hand, the blind believer in the *vis medicatrix naturæ* waited till the stage of exhaustion had set in, and his excision often failed. He thought the cases before the Society spoke for themselves.

DR. ESLER thought the operation not only justifiable, but, in carefully-selected cases, imperative. The successes here, he thought, proved that the cases were judiciously selected; he agreed with Dr. Wheeler that many excised before there was justification for such a proceeding.

The Secretary reported the decision of Council about Honorary Members (to be dropped) and the paper with the remarks will appear in the transactions.

Richard Ross

Session 1876–77.

Ninth Meeting 1st May 1877

Present, Dr. Ross (in the chair) Dr. Wheeler, Drs. Wales, O'Malley, Strahan, J. W. Browne, Esler, Whitla, D. Johnson, McIvor.

Dr. Harkin read a paper on cases of hydatidiform mole pregnancy and exhibited specimens.

Paper:¹ MR. PRESIDENT,—Mrs. C. Stewart, aged twenty-two, the patient from whom the specimen before you was discharged, sent for me on the evening of Monday, 16th April last. I found her complaining of great stomach sickness, of debility, and of an abdominal tumour, for the relief of which she informed me that she had passed the previous three weeks in a special hospital, having left only on that morning.

I deferred any further examination till daylight, and again saw her on Wednesday, 18th ult.; she was then pale and anæmic; had an extensive ragged ulcer on the os uteri, and a tumour of pyriform and symmetrical shape, soft and elastic, extending from the pubis up to and several inches beyond the umbilicus. Her breasts were enlarged and painful. She informed me that she

¹ [Dublin Journal of Medical Science. 1877, v64, p330.]

considered herself pregnant from November, 1876, having to wean her child in consequence; had great sickness of stomach from January; and that, on July 15th, after a smart hæmorrhage, she had discharged a fleshy substance the size of an egg, evidently the embryo. Her health then got worse daily, and she continued to enlarge up to the moment I saw her. Being satisfied, from the history of the case, from the physical signs, and from my previous personal knowledge of the patient, that I had a case of vesicular degeneration of the chorion villi and placenta, I prescribed an infusion of *secale*, given in repeated doses; slight pains began soon to show themselves, accompanied with some hæmorrhage; and, at the end of a week, I found her weak, having voided large clots, and with strong expulsive pains. Finding the os uteri enlarged, I dilated, and, with pressure from the left hand over the fundus, about three pints of pearly vesicles came away, some of them buried in the nidus of a degenerated portion of placenta. I then ordered some stimulants, and fluid ext. of ergot, which soon put a stop to the hæmorrhage, and the patient is now progressing favourably to recovery.

Her previous history is instructive:—She was married in December, 1874, and became pregnant in the beginning of the next year; she sent for me in April, 1875, for a flooding that had commenced in the March previous; for this she got relief; I saw her again early in June, when she presented an appearance similar to that described to-night; and on 23rd of same month she discharged about two pints of pearly-like vesicles, nearly as large as grapes, and, like that fruit, attached by pedicles to a central stem. After this occurrence she menstruated regularly for nine months, became again pregnant, and gave birth to a living child at the full period. I should not be astonished to learn that she had completed a similar cycle in three years hence, and, perhaps, afforded subject for a similar communication to some learned body like your own.

I can refer to a third case which occurred in a very healthy woman twenty years since, the mother of several children, the first step in which case was a slight accident producing uterine hæmorrhage, and some three months afterwards a discharge of those peculiar bodies I had then preserved in turpentine, as I show them, but they are now dried up and not very instructive. In a fourth case of mole, which I watched for four months after the loss of the embryo, the patient passed a large heavy substance like gutta-percha; the placenta increased, and hardened by deposits of very firm material. As to the causation of those abnormal bodies, most medical authorities affirm that they are the products of conception, and not at all of the nature of the true hydatid. It is to Cruveilhier that the credit is due of first making this distinction. The most general opinion agrees with the teaching of Barnes and Graily Hewitt, that the disease consists in a perverted development force; and that after the detachment or destruction of

the embryo, the chorion villi, continuing in connexion with the uterus, maintain a slow growth; and that the vesicular bodies are thus the result of dropsical swelling of the chorion villi.

DR. M'IVER asked Dr. Harkin's opinion as to whether the death of the embryo was the cause of the hydatids or the converse.

DR. WHEELER approved of the treatment with ergot, and thought that the vesicles were produced after the death of the fœtus; he had met three cases in practice.

DR. HARKIN was of opinion that the blood which went to form the fœtus went to form the hydatids after its expulsion.

Dr. J. W. Browne in the absence of Dr. James Moore exhibited the larynx of a case of cut throat.

Richard Ross
May 30 1877

Session 1876–77.

30th May Tenth Meeting

Present, Dr. Ross (President), Drs. Wheeler (Ex-President), Wales and J. W. Browne (Vice-Presidents), Fagan (Treasurer), Whitla (Secretary), McConnell, Coates, (Newett and H. Purdon as visitors). Dr. Esler.

Dr. Whitla exhibited a patient upon whom the operation of amputation through the hip joint had been performed some 2 years previous.

Paper:¹ Dr. Newitt, under whose care she had been, being present as a visitor, the Chairman asked him for the history of the case.

DR. NEWITT then read the following notes:—

Mary Millar came under notice, for the first time, on April 3rd, 1873. She was then suffering from severe erysipelas of thigh, from which she recovered, having been treated with iron.

On June 16th, of same year, fracture of the thigh occurred while in the recumbent posture. The fracture was the result of scrofulous disease of the femur.

The limb was put up in as easy a position as possible, without any idea other than that of ease and comfort to the patient, as her health was so low that a termination in death seemed inevitable. She was in every way, made as comfortable as circumstances allowed of. Medicines were given to sooth and support. In the course of some weeks the broken ends of the femur made their way through the integument in front of the thigh. The smell of the decomposing bone was very bad, and it was with difficulty that the air of the apartment could be kept pure—iodine, allowed to evaporate, and Condy's fluid were used for this purpose. She became much emaciated and extremely feeble, and continued so for months. Death appeared certain. The treatment was simply directed to her comfort. Great care was taken to prevent bed-sores, to keep the atmosphere pure, to

¹ [Dublin Journal of Medical Science. 1877, v64, p443.]

soothe her; and tonics were given when admissible.

Matters continued, as described, until January, 1874. During that month hæmoptysis occurred, and there was crepitation at the apex of one of the lungs. Gallic acid and sedative mixtures were used in treating the hæmoptysis.

During the summer of 1874 she improved a good deal; and the idea of removing the limb first occurred to me. The idea was, however, given up, in consequence of her health again failing. She commenced again to improve during the winter of 1874. I determined—her consent having been obtained—to prepare her for an operation, which should take place with as little delay as possible. I recollect being delighted that her stomach tolerated cod-liver-oil. I gave her this remedy, also a mixture of quinine, perchloride of iron, and in sol. chl. potass, also sedatives; and I looked carefully after the purity of the atmosphere.

On the 13th February, 1875, Drs. M'Connell, Whitla, and myself, proceeded to amputate the limb at the upper third of the thigh. The patient was extremely emaciated, although improved from what she had been some months before. When we were about to proceed, the question arose whether or not we should. The patient's desire for the operation, and the conviction that it was her only chance for life, the continuation of which—with the inability to move out of bed, necessitated by the presence of an extensively diseased limb, with a large mass of decomposing bone, which was polluting the atmosphere—was very cheerless; this consideration, I say, convinced us that it was our duty to operate.

Dr. Whitla having applied Esmarch's bandage, Dr. M'Connell most carefully administered chloroform. I made the flaps anterior and posterior, in the upper third of the thigh, by transfixing and cutting downwards. We found all of the tissues brawny and infiltrated; the bone was like a piece of rotten stick, as thick as a finger; I cut it through with a scalpel. I then proceeded to assist Dr. Whitla, who was attending to the arteries. He grasped the femoral artery with a forceps; I tied. The artery was brittle and apparently infiltrated with scrofulous matter; it broke with the tying like a piece of pipe-shank. The case looked hopeless. We felt certain we should leave her dead behind us. Dr. Whitla dissected the artery up about half an inch or more, and succeeded in tying it. Dr. Whitla then proceeded to remove as much of the diseased femur as possible, and ended the operation by disarticulating and removing the head of the femur. The flaps—which had been extended by me—were then brought together and dressed. About one hour after the operation the patient commenced to vomit. The vomiting continued, interrupted only by snatches of sleep, until the following Friday morning—the operation was performed on a Saturday. Administration of any aliment or medicine by mouth was impossible, as the presence of a piece of ice

on the tongue intensified the vomiting. I became most excited and interested in the case; and, whenever I was disengaged, I ran up to see her. I injected milk into her bowel several times each day. The vomiting having ceased, her stomach retained a little milk and lime-water. The emaciation and debility, at this time, were indescribable.

Having commenced to improve, she—to use an expressive phrase much used—“never looked behind her.”

DR. WHITLA had assisted Dr. Newitt, and thought the notes read did not certainly overdraw the picture of the difficulties which presented themselves. As had been stated after the incisions were made, and the scalpel went through the bone, in making them Dr. Newitt asked him to take charge of the head and neck of the femur which he grasped with the lion forceps and disarticulated, a very easy matter, as the bone was extensively diseased, and came away in pieces; he then found that the acetabulum was diseased, and a sequestrum could be felt lodged in its floor. Going out to the county for an amputation of the thigh, as Dr. Newitt had written to him, it never occurred to him to bring a gouge with him, so he used the handle of the lion forceps as a gouge, and removed the greater part of the acetabulum till the finger, introduced into the bottom of the wound between the flaps, struck upon the thickened pelvic fascia.

The flaps being made for upper-third amputation were much too long, and their appearance was characteristic; they were riddled with old sinuses, and just looked like conical slices cut out of an amyloid liver, in which one could scarcely recognise any structure. In this lay the femoral artery, and the spot at which it was eventually tied, after two attempts, was close under Poupart's ligament. The aspect of affairs at this stage was, as Dr. Newitt says, truly indescribable, and I must say that though the result is excellent, if I knew I could foresee every difficulty as they now rise vividly before me, I would be very slow in undertaking such again.

Before and after the operation the case seemed to me almost hopeless, and it was only Dr. Newitt's strong sense of duty, and the feeling that he must make some effort to prolong life, that caused the operation to be consented to, and I have no doubt death must have followed but for his self-denying exertions in the after-treatment.

The patient having undressed, the stump was exposed, and presented an excellent appearance; the low inflammatory deposit in the flaps had disappeared, and the parts looked as in a typically successful amputation through the joint. The patient was strong and healthy, and able to earn a livelihood.

Dr. ROSS congratulated Dr. Newitt, and those who gave him their aid, upon the issue of the case, from Dr. Newitt's and Dr. Whitla's description, and what he saw, the success was a very decided one; he looked upon

such a result as a triumph of surgery. The stump was excellent.

He agreed with Dr. Whitla that the after-treatment had much to say with the result; and he thought the free mountain air did a great deal.

DR. DEMPSEY was surprised that no serious consequences followed the removal of bone in the acetabulum.

DR. ESLER made some remarks about the flaps; he had on one or two occasions noticed a flap liquify—literally melt away—when infiltrated as these were, and consequently he would not hesitate to operate on this account.

DR. BROWNE, in speaking about the flaps, reviewed the different operations at the hip-joint, and advocated the anterior and posterior ones. From the history of the case he thought it possible that the cause of fracture was owing to acute necrosis; in this Dr. Coates and the Secretary joined him.

DR. WALES was gratified to hear the details of this case, and commented upon the operation and its difficulties. He thought the persistence of the enemata treatment deserved great praise, and had much to say to the result, which was brought about by the entire removal of all the diseased bone.

DR. M'CONNELL said, during the operation he thought the patient was at one time over from the chloroform; he was surprised at the time at the small quantity of blood lost—this was owing to the way the elastic ligature was applied, being more round the pelvis than the thigh, and above the ischial tuberosity.

Dr. Whitla exhibited from patient who had worn a tracheal tube 46 years, the trachea and larynx which he had removed after death.

Tracheotomy had been done 46 years previous by Dr. H. Purdon who being present as a visitor gave the early history.

Paper:¹ The Secretary (DR. WHITLA) exhibited a larynx and trachea which he removed from a patient a few days before, upon whom the operation of tracheotomy had been successfully performed about forty-six years previously, and a tube worn all that time. Dr. Henry Purdon was the operator, and as he was present he would call upon him to kindly give some particulars of the early history to the members of the Society. The specimen showed a healthy air-tube in every respect, save the little aperture into the trachea where the skin and mucous membrane became continuous. He had dissected the muscles carefully, and found all those attached to the hyoid bone normal in every way except the omohyoid, which was reduced to the size of a mere thread; he thought this worth noticing, as the function of the muscle was not satisfactorily known. The interior of the larynx was healthy, all traces of inflammation

having disappeared except the contraction, which had probably followed cicatrisation, leaving the lower aperture of the larynx so narrow as only to admit an ordinary probe.

DR. HENRY PURDON said:—This case has been fully related in the twenty-fourth number of the first series of the Dublin Journal, and was written at the request of the late Mr. Carmichael. The tube through which she breathed may seem dangerously long, and likely to injure the posterior wall of the trachea, but I found the sterno-hyoid and thyroid muscles rendered a shorter one inefficient, and a curved one was worked out by the action of these muscles. Of course the tubes used were double, but this is the inner one of the third or fourth set which have been worn out since the operation was performed. I may mention that I found it necessary in the earlier ones to have a slight collar or rim round the inner extremity of the outer tube to prevent its being worked out.

COMPILER'S NOTE

The following report seems likely to be the one mentioned above although Dr. Purdon was not the operator. It is the fourth case in Mr. Richard Carmichael's paper "Observations on the Use of Tracheotomy in Chronic Diseases of the Larynx, Illustrated by Cases."¹

The next case I shall lay before the public is one of high interest; it is an instance of chronic laryngitis arising from repeated attacks of catarrh in a person probably predisposed to the complaint, as she was all her life subject to hoarseness, whenever she caught cold. The patient, a lady about fifty years of age, resides in Belfast, to which town I was called to see her in the beginning of last May. I found her seated in an arm chair, breathing with great difficulty, and making deep and long sonorous inspirations, of a croupy character; she had not been able to lie in the recumbent position for several weeks, and her legs were swelled and œdematous as high as the knees; on examining her and inquiring into the history of her complaint, I instantly came to the decision that nothing could save her life but tracheotomy, which I accordingly performed the following day, assisted by Mr. M'Cluney and Doctor Henry Purdon, both of Belfast.

For the following history of the case I am indebted to the latter gentleman:—

Belfast, August 10, 1832.

My Dear Sir,

For the last two years our patient, Miss B's breathing has been slightly affected when ascending a hill, and whenever she caught cold her voice was husky; last August, after a slight attack of catarrh, her voice continued weak, which however gave her no uneasiness, as

¹ [Dublin Journal of Medical Science. 1877, v64, p446.]

¹ [Dublin Journal of Medical and Chemical Science, 1833, v2, p159.]

she expected that it would, in a little time, return to its former strength; but, in December, her friends becoming uneasy, the gentleman (Mr. M'Cluney) who attended the family was consulted; her voice then was almost completely gone; she had occasionally a cough; the larynx was rather tender on pressure; the respiration slower than natural: deglutition difficult at times; pulse slow and regular; sleep, appetite, bowels, and strength perfectly natural; leeches were frequently applied to the neighbourhood of the larynx, also blisters and various expectorants.

I saw her about the middle of last February, her voice was then stridulous, or rather a low whisper, and the cough and inspiration were very like what I have heard in the advanced stage of the croup, attended with a sensation of tightness in the larynx.

She went to Dublin in the latter end of the same month, and during the journey her breathing was much easier. After consulting Mr. Colles, she returned towards the middle of March, and immediately commenced using the medicines he had ordered, which were, mercury internally, and a stimulating liniment externally; her mouth became sore in about eight days, and was kept so for twenty-four, and then, as she found herself rather worse, the mercury was omitted, and the mouth allowed to get well; during the time it was sore, small portions of mercurial ointment were rubbed in along the side of the thyroid and cricoid cartilages, with the double view of keeping up the general action of mercury on the system, and at the same time of exciting local counter-irritation; after this a very stimulating gargle was used, which increased the flow of saliva, and caused great irritation, without, however, producing any amendment; lastly, a solution of the nitrate of silver was applied to the lower part of the pharynx, by means of an elastic tube, through which a piece of wire was passed with some lint dipped in the solution (the strength of this was ʒss ad ʒi). Every application caused a severe paroxysm of dyspnœa, and as there was no amelioration, but a gradual increase of dyspnœa, after having been repeated ten or twelve times, it was omitted. We now tried frictions with iodine ointment; but this she was unable to bear, from the severe irritation it caused on the skin.

At night she had paroxysms of orthopnœa lasting for perhaps four or six hours, and for this she took various anti-spasmodics, all of which relieved her for once or twice, and then failed; during the day she was always better, and when the weather permitted, went out in a carriage, and while there was invariably better, the inspirations being much easier and less noisy. Towards the end of April her feet and legs began to swell, and she was unable to lie down at night, but the pulse still continued about seventy-four and good, and the lungs appeared sound, the inspirations twelve in a minute.

You first saw her on May 4th; then the dyspnœa was

very urgent; her pulse seventy-eight, rather weaker than before; lungs sound, both on auscultation and percussion; slight tumefaction on both sides of the larynx. You operated on the 5th, making the first incision with a bistoury; there was a great deal of fat under the integuments; no vessel was divided; that night she slept a little, and was easy next day; on the 7th her breathing became much oppressed, and as the wound and adjoining integuments appeared much swollen and inflamed, you directed a number of leeches to be applied, which caused an oozing of blood during almost the entire night, and was followed by great and decided relief; afterwards, her amendment was steady and progressive; she breathes freely through the wound, which we are obliged to keep open with two concave plates of silver, that form a tube when pressed together, but she is incapable of speaking.

In a note, which I received from her this day, she says: "That my general health is quite good; rest, appetite, and strength, all excellent; but I am dumb, and shall remain so for life."

At present she cannot inspire at all by the natural opening. Should this account not prove satisfactory, it will give me great pleasure to fill up any omissions, or write another if you wish, and believe me, dear Sir,

Your truly obliged,
Henry Purdon.

Now, although I admit it is a great misfortune for a lady to lose her voice, yet it would be much greater to lose her life, which must have been inevitably the case had not the operation been performed. Besides, the loss of voice cannot be altogether laid at the door of the operation, for it was all but lost before that measure was resorted to. For all the other cases of affections of the larynx, either acute or chronic, upon which I performed tracheotomy, the voice was gradually restored as the inflammation and swelling of the larynx subsided; the wound in the trachea, notwithstanding the removal in every instance of a portion of the rings, progressively closing as the obstruction to the passage of air in the larynx diminished.

In the present instance, the same happy result would, no doubt, have ensued, had not the obstruction to the passage of air been owing to a chronic and thickened state of the lining membrane of the larynx, so obdurate as not to yield to the plastic power of the absorbents, even when the artificial opening in the trachea allowed the affected organ to remain in a state of quiescence.

With the view of reducing this thickened state of the mucous membrane, inhalation of iodine was resorted to, but without success.

The patient had been, as was mentioned before, all her life predisposed to chronic laryngitis, as her voice was naturally husky, and whenever she caught cold she was subject to obstinate attacks of hoarseness.

The members present congratulated Dr. Purdon upon the extraordinary success of his operation. No one had heard of a case where the patient survived fifteen years [sic] and continued to require the use of the tube.

Case of Fibrous Tumour.¹

DR. JAMES MOORE exhibited a drawing of a tumour recently removed from a man thirty-six years old. It was firmly fibrous in structure, and weighed 16 ozs.; it extended from behind the ear to the chin, pressed upon the trachea, interfered with deglutition, and disturbed the heart's action. He described the steps of the operation, which several members had witnessed performed with great dexterity. The wound healed rapidly. The tumour was dissected off the facial artery, in a long part of its course.

Dr. Whitla also exhibited a limb removed the same day [by Dr. Newitt] for disease of knee joint.

George F. Wales

Session 1876 77.

Annual Meeting Wednesday November 7th 1877

Present, in the chair Dr. Wheeler, Drs. Dill, John Moore, Dempsey, Core, McConnell, McKee, Coates, Esler and Whitla.

The Secretary read the report of the Council which was adopted and it was agreed it should be printed and appear in the volume of the transactions.

ANNUAL REPORT¹

The Council have much pleasure in submitting to the Members of the Society their Report for the year just terminated.

Ten Ordinary Meetings, in addition to the Annual Meeting, were held, and the average attendance of Members was thirteen.

The Council met seven times, and the following is the attendance of Members:—

Dr. Ross,	6	Dr. Core,	4
Dr. Wheeler,	4	Dr. Fagan,	4
Dr. Wales,	2	Dr. Murney,	3
Dr. Brown,	4	Dr. John Moore,	3
Dr. Coates,	6	Dr. Spedding,	3
Dr. Beck,	3	Dr. Whitla,	7

The Council regret to record the death of one of the most promising Members of the Society, Dr. M'Crea, who had been for many years an active Member, and whose genius and brilliancy had shed much light upon the discussions of the Society. His papers, characterised by great originality and research, show that he has left behind him foot-prints which are fixed and lasting. Upon doubtful and obscure cases brought before the Society, his clear judgment and logical decision were listened to always with marked respect and esteem by the senior Members; and the Society mourns the loss of one cut off at a comparatively early age, who, had he been spared, would have taken the highest place in his profession.

Regarding the work done by the Society during the last year, Council think the results will compare favourably with those of years gone by, as the following will show:—

Thirteen papers were read.

Dr. Coates—"Notes of Cases of Acute Rheumatism treated by Salicylic Acid."

Dr. Beck—"Notes of Cases of Tertiary Syphilis."

Dr. Browne—"Case of Tapping the Bladder in Two Places, per Rectum, and above the Pubes."

„ "Case of Fracture of Lower Jaw treated with Silver-wire Sutures."

Dr. Murney—"Notes of a Case of Successful Ovariectomy."

Dr. Fagan—"Paper on Excision of the Knee-Joint."

„ "Notes of Case of Malignant Cerebral Tumour."

Dr. Spedding—"Notes of Cases of Puerperal Eclampsia."

Dr. Esler—"Oakum as an Antiseptic Dressing."

¹ [Dublin Journal of Medical Science. 1877, v64, p447. To be found immediately after the tracheotomy case but not recorded in the minutes of the Society.]

¹ [Offprint from the Transactions found in the Minute book.]

Dr. Harkin—"Notes of a Case of Recurring Hydatidiform Mole Pregnancy."

Dr. Whitla—"Notes of a Successful Case of Amputation through the Hip-Joint."

Dr. M'Keown read two original papers—one upon "A New Operation for Trichiasis and Entropion," and one upon "A New Operation for Detachment of the Retina."

PATIENTS EXHIBITED TO THE SOCIETY.

Dr. Fagan—A Case of Partial Removal of Tarsus, and Three Successful Cases of Excision of the Knee.

Dr. Browne showed the patient upon whom he had operated for impermeable stricture, by tapping the bladder.

Dr. Whitla showed a patient upon whom an amputation through the hip-joint was performed.

MORBID SPECIMENS EXHIBITED.

Dr. Murney—An ovarian cyst, and a compound fracture through knee-joint.

Dr. Coates—A brain from an apoplectic subject.

Dr. John Moore—A larynx from a suicidal cut-throat.

Dr. James Moore—A fibrous tumour.

Dr. Beck—A vertebra expectorated by a syphilitic subject.

Dr. Whitla—A diseased knee-joint; and a larynx and trachea from a patient who had worn a tracheotomy tube forty-six years.

Dr. Harkin—Hydatids, uterine.

Some of the papers were illustrated by crayon and water sketches and photographs.

The Transactions of the Society have been forwarded to the Dublin Journal of Medical Science, and through the kindness and courtesy of the Editor, Dr. J. W. Moore, have all appeared in its columns without abbreviation.

The Council report, with pleasure, that during the past session no less than nine Members joined the Society. This fact, with the consideration of the amount of work done, leads them to hope that the coming Session will be one crowned with success.

A Microscopic Committee has been formed, consisting of—

Dr. J. W. Browne,
Dr. Fagan,
Dr. Wales,

Dr. Coates,
Dr. Core,
Dr. Whitla,

the latter to act as convenor; and the Council hope that the Members of the Society will avail themselves of this Committee, and that some practical work will be transacted in this very important field.

The Secretary hopes to be able to place in the hands of each Member next month a complete copy of the Transactions of the Society.

The Report was adopted; and, after the usual votes of thanks to out-going office-bearers, a ballot was taken, and the following gentlemen were appointed to act during the Session of 1877-78 ...

Arrangements were made for the Annual Dinner and the following office-bearers elected:

Dr. Wales, **President.**

Aickin and J. W. Browne, **Vice[-Presidents].**

Council: F. E. Beck, W. S. Core, John Moore, A. McConnell, R. Esler, S. B. Coates.

F. Fagan, **Treasurer.**

W. Whitla, **Secretary.**

Workman, Chas., M.D., M.Ch. (Q.U.I.)

Session 1877-78

First Meeting.

The first ordinary meeting of the Society was held in the theatre of the Belfast Royal Hospital on Wednesday evening at 8 p.m. December 5th 1877.

Present, Dr. Wales (President) in the chair, Dr. Browne (J. W.), Dr. J. W. Beck, F. E. Beck, Cuming, Dill, John Moore, Fagan, Wheeler, D. Johnston, Speer, Stra-

han, Spedding, Harkin, O'Malley, Esler, Coates, Dempsey, Whitla, Jefferson, O'Neill, Clements.

A ballot being made, Dr. C. Workman was unanimously elected member of the Society.

The President then read his inaugural address.

Paper:¹ GENTLEMEN—In entering on the presidential duties of the session, let me thank you for the honour you have conferred on me—an honour which was unlooked-for, and which I value the more because of its coming from you so unanimously. It is gratifying to a man after a life's labour to find that he is considered worthy of such a spontaneous tribute of respect, for next in satisfaction to that afforded by the mens conscia recti is that resulting from the approbation of one's professional brethren. I wish I could feel that I really merited such favourable consideration. I can but strive to prove in some degree worthy of your kindness.

I have to acknowledge gratefully the many promises of co-operation in the work of the Society from members generally—from some of my respected predecessors in office, and from my seniors in the profession. With such support, and your indulgence for my shortcomings, I hope, aided more immediately by the staff of the society and its able and indefatigable Secretary, to see its usefulness preserved, and, if possible, extended in the coming session.

It is now more than a quarter of a century since I entered on the duties of my profession and joined the old Medical Society of Belfast. About this time men began to shake themselves out of the old grooves of thought. Physiological, pathological, and chemical research took on more activity, a spirit of inquiry and criticism spread abroad, leading not only to a disposition to break new ground, but also to test the foundations of received opinions and established practices. Amongst the foremost in this town to catch the spirit of the time was the late Dr. Malcolm. He founded the Pathological Society here, not to supplant but to supplement the Medical. I had the honour of acting with him as joint-secretary during the first year of its existence.

It turned out remarkably successful. Its meetings were held weekly, and were well attended by members of the profession old and young, from town and country. Queries were regularly propounded for discussion, and formed a prominent feature in the working of the Society. These always excited interest, the members generally taking part in the discussions, which were published. No man ever did more for the profession in Belfast while he lived than did Dr. Malcolm. Like a little leaven he leavened the whole mass with the spirit which animated himself, but he died too soon, and left a void in our rank which was long felt. After his death the Pathological Society maintained its usefulness for a time, but gradually it waned, and finally merged with

the Old Medical into the "Ulster Medical Society." We thus combine the two, and considering that much of the old matured element is still with us (a consideration which inspires me, in passing, to hope that former presidents will occasionally manifest by their presence and countenance the interest they once felt and promised in our welfare), and considering the superior character of the new element, it will not reflect creditably on either if we have a sluggish and unprofitable session.

In closing this special reference to our Society, it is with unfeigned sorrow I notice, at this our opening meeting, the absence of a once familiar pleasant face. I refer to the late Dr. John McCrea. We will miss him in the work of the Society, in which his ability, attainments, and cultivated experience made him so valuable; and we will miss him otherwise, for the high tone of honour and genial fellowship which characterised him and made him a favourite.

The last quarter of a century has been a period of transition and progress. No similar period in our history has been so eventful, so revolutionary, so humbling to assumption of power, and yet so satisfactory in point of work done. At the commencement of the time referred to we still pursued the vigorous methods of combating disease which belonged to the previous generation, chief of which was blood-letting. In my early years few days passed without my using the lancet, and yet it is now several years since I performed venesection. At first sight it will appear either that we were wrong then or that we are wrong now. I believe the lancet was too much used before, and is unjustifiably neglected now in deference to modern views. I can well recollect the great and permanent relief so frequently given by the lancet in acute serous inflammations, pneumonia, and congestive head affections; and yet it is so forgotten now that I venture to say a great many of our younger brethren have neither bled nor seen bleeding throughout their whole career. Some explanation of the difference in practice at the two periods is afforded by the recollection that formerly it was quite the habit to be bled annually. However such an injurious practice came about I do not know, it begot a plethoric condition which maintained the demand for periodic depletion, owing to the relief that always followed. About the time that bleeding began to be called in question, or rather a little prior to it, very active medication was as much the rule as bleeding, so that patients, I may safely say, were seldom lost by inaction; but with the growth of homœopathy there came a change in our views. Notwithstanding all the irrational assumptions of that system, it secured many adherents amongst the better classes. It fascinated them by the simplicity of its law, by the possibility of their grasping the symptoms, and selecting easily the assumed remedy by a reference to its alleged effects. It satisfied thus that craving for amateur doctoring which so universally

¹ [Dublin Journal of Medical Science, 1878, v65, p65.]

prevails. Then, again, the sugar globules and fanciful dilutions were not unpleasant to taste like our medicines. They did not sicken, and whatever other effect they had or had not was supplied by the imagination. But under homœopathy and hydropathy, another rival system of therapeutics, it was found that patients did very well. Medical men were not slow to discover the truth. They perceived that nature could be safely trusted to manage a good deal of her own business, and that she did manage it in every case treated homœopathically, except so far as the admirable dietetics of that system, and the mental impression contributed to the result. The lesson had its influence. It was found that disease could be dealt with without such active drugging as had been in vogue, and faith and empiricism gave way largely to scepticism and rationalism. The reaction from the excessive use of drugs, like bleeding, led, in the tendency to extremes, to much unjustifiable neglect of therapeutics.

It is right to be as rational as we possibly can in the treatment of disease, but the practice of medicine must always remain largely empirical, and we must not undervalue it on that account. The experience of our fathers should receive our most respectful consideration. If they had not the same light to guide them that we have now, it did not hinder them from doing good work. They certainly were great in powers of observation. They have portrayed disease for us, in nearly all its phases, with singular truth and fulness, and they have given us the great bulk of the medicines we possess, with an accurate description of their effects. That was their work.

Ours is to develop the causation and pathology of the one, so as rationally to utilise the other. In other words, by an improved knowledge of the causes and conditions of disease, to select remedies that will apply to them in preventing or mitigating their operation rather than such as may only influence the symptoms and signs. The more we can succeed in doing this, the more scientific and rational will be our practice. That we are gaining sure footholds in the path of knowledge, and making rapid advances cannot be doubted. True these advances are sometimes made at the sacrifice of much that was considered well established; for example, it is disconcerting to be told that the idea of a limited brain area for each special sense is no longer tenable; that if any such localisation exist, it exists in cells diffused pretty generally through large extent of brain substance.

We can no longer say in a case of aphasia, anæsthesia, or motor paralysis, that the lesion is absolutely so and so, for we know that, apart from any lesion, mere irritation, remote as well as direct, will induce any or all of these; and, further, we know that such conditions may be maintained indefinitely by some inhibitory influence, often slight, the removal of which will again bring into play the functions of the uninjured generat-

ing and conducting nervous structures. In point of practical value I believe that no investigations of late excel those made by Professor Lister. It is a great step in knowledge to know that animal fluids and secretions have not any inherent tendency to putrefy—that they will remain in contact with pure air—i.e., air freed from living germs, without change; that such change when it takes place is a true fermentative process—i.e., a change due to the growth and development of living germs.

I think the Professor has absolutely demonstrated these points by his recent experiments, and that those who have asserted that the ferment (so called) may be a chemical and not a vital agent, have failed in their proofs. Great as have been the advantages resulting to surgery from the application of this knowledge, I believe that greater will be realised in medicine when the various morbid blood conditions come to be better investigated.

Having lightly touched on questions peculiarly our own, there remains one which is of general importance and interest, and which, I think, from the increasing magnitude of the evil, we, as guardians of the public health, have not only a right to speak out on, but I think we are morally bound to do so. I allude to the growing evil of intemperance. I cannot conceive any subject more important or more worthy of our earnest consideration. I am sure I am only speaking your experience when I say from my own that amongst men, and not inconsiderably amongst women of all classes, the use of strong drink as a beverage has produced much of the disease we have had to treat, not to speak of greater evils even than disease.

Speaking for myself, I would say that alcohol in any form is unnecessary in health, and injurious, unless taken in great moderation; that when so taken it should only be in connexion with food, and not before dinner; that those who have not been accustomed to it should not lightly begin it; that youth should take none. It is difficult to see how young persons can be preserved as long as stimulants are habitually used at table. I was much impressed while in the United States recently by observing the general absence of liquor on the tables in the dining halls of the large hotels. Persons who wished for drink had to go to the bar for it.

This was a great protection to youth and weak persons of both sexes, and might be imitated with advantage amongst ourselves. Beyond the class likely to be in any degree influenced by suggestions from us, there are the great classes which will never move to save themselves. They resort to public-houses, not to refresh, but to get wholly or partially drunk. If it is wrong for the respectable man to drink before dinner, why should the poor wretches who have lost self-control in the matter of drink be allowed to drug themselves to ruin and death, either for the profit of the State or individuals? Things are not right.

Let the clergy speak out boldly, and tell their people of the moral degeneracy that drink is producing. Let our legislators and magistrates endeavour, not less to diminish the facilities which they have created and sanctioned, than to punish those who, tempted by such facilities, become victims. Let philanthropists generally who desire to accomplish the greatest good for their fellows and their country, try to save the rising generation from intemperance, protect the weak, and render the irreclaimably inebriate as harmless as possible.

Let us aid the philanthropists and others, by our influence and advice, and by our declaring what we know of the effect of alcohol as a beverage. With its use as a medicine in our hands the public have nothing to do, and would wisely take nothing to do. Our experience will guide us better than theorising and assertion. The whole question is on the paper for discussion. One of greater gravity and importance there cannot well be, and I commend it, gentlemen, to your earnest consideration, with the view to some practical issue in the public interest.

Dr. Wheeler, in proposing a vote of thanks to the President, said that as Dr. Ross, the President for last year, was not present, he took the privilege to move, "That the best thanks of this Society be given to our President for his very interesting and able Address." The subjects he had touched on had been well discussed. He sincerely agreed with him in all that he had said in reference to the views he had enunciated on the subject of intemperance; but as the question came on for discussion, he would say nothing but merely assume the privilege of proposing the resolution.

Dr. Cuming said he had very much pleasure in seconding the motion. The Address had been full of instruction—thoughtful, reflective, and characteristically practical. In the early days of the old Pathological Society, Dr. Malcolm and he were colleagues in the Secretaryship. They had since seen its decline and the rise of the present one. Perhaps they were about to witness the advent of another. He knew the members would be most happy to give every assistance to this Society during the present session, and they knew very well that its proceedings would be presided over with great impartiality.

Dr. Dill, in supporting the motion, wished to refer a little further to what the President had so elegantly spoken of. Inasmuch as he had named Dr. Malcolm as having thrown life and soul into the then Society, he would be disposed to name another gentleman who certainly at a period a little prior to that did give very great life and spirit to the old Medical Society of Belfast—he alluded to Dr. Saunders. His knowledge of the Society at that early period led him (Dr. Dill) to say that he was then what Dr. Malcolm was described to be at a later period. As a matter of historical fact Dr.

Saunders was the first who ever read a paper on any medical or pathological subject before the old Society.¹ He thought it was right this should be placed before them. In speaking of former members, Dr. Saunders was, on the one hand, an eminent surgeon of the hospital, and Dr. Malcolm a physician of it. They were two who gave life to the profession, and entered on their labours with an energy and disposition which he would like to see amongst all their junior professional men.

The motion was carried by acclamation.

Dr. Esler moved Dr. Lindsay as a member of Society. Dr. Wheeler seconded.

Dr. Coates proposed and Dr. Whitla seconded Dr. Jefferson's nomination as member.

Dr. Dill proposed and Dr. Esler seconded Dr. Clements.

Dr. Whitla proposed and Dr. Wheeler seconded Dr. O'Neill.

Dr. Esler gave notice of motion that he begged to propose that the resolution of last session, by which the periodicals were left on the table for a week, be rescinded. He believed that the objects of the mover and seconder of that resolution had not been effected.

Dr. John Moore opened the debate on "Alcohol—Is Its Moderate Use Beneficial or Injurious?"

Paper:² How much hangs on a true answer to that question! That the immoderate use of alcohol is injurious there can be but one opinion; but that men believe in the beneficial effects of the moderate use of alcohol is testified by how much they pay for it—millions of money, oceans of tears, thousands of desolated homesteads, and countless broken hearts are freely flung into its treasury, as the price paid for the beneficial effects supposed to arise from its use when taken in moderation.

I may state at the outset of my remarks that I am not competent to enter upon a discussion of those experiments which have been carried out by practical physiologists and expert chemists on the action of alcohol on the elementary tissues of animal bodies. I may accept the teaching on these points of those fitted to deal with these subjects, and confine myself to the empirical experience gathered over now many years.

The subject presents almost an insurmountable difficulty at the very outset, as we have no "standard of health" to which we can refer—the different amounts of energy or vitality is so varyingly bestowed. One can walk a thousand quarter miles in as many consecutive periods of ten minutes each, and be vigorous at the end, while another would break down under the tenth of the task. On some the climatic state has a powerful effect—bright sunshine, clear frost, brisk breezy days producing a glow and imparting energy, buoyance, and cheer-

¹ [Not correct. See page 4.]

² [Dublin Journal of Medical Science, 1878, v65, p69.]

fulness, whereas dark, gloomy weather sheds the same sombre hue over the spirits, and depresses vitality to the lowest point of health.

The construction of the nervous organism in some is formed on such a high key that every thrill that sweeps across it causes it to vibrate with hyperæsthetic sensations; these know how

Dearly-bought the sudden treasure
Finer feelings can bestow,
Chords that vibrate sweetest pleasure
Thrill the deepest notes of woe.

These are the individuals more susceptible of the influences of alcohol, and more in danger of being drawn into its snares. Others, again, are so anæsthetic that what to the former class would be torture they bear with calm placidity; in these the resisting power is great. The "moderate" use of alcohol presents the same difficulty; it is an elastic measure, not a fixed standard. Where does it begin, and where does it end? Moderation in alcoholic stimulants to one individual is downright drunkenness to another. I know some on whom a single glass of sherry has such an effect as to be quite apparent, and I know others who could carry a bottle, and yet manifest no symptoms of being overburdened. On endeavouring to analyse one's own feelings and sensations on partaking, when the appetite has been sharpened by outdoor exercise, of a tender, well-cooked beefsteak (accompanied with its usual accompaniments, by mealy potatoes with good bread)—these, aided with a bottle of Bass or Allsop's, produce a pleasure in the participation, a feeling of satisfaction afterwards, and an amount of invigoration following as to make one hardly care to call his king a cousin.

The intoxicating effects of the tumblerful of beer is quite perceptible, and lasts for a few minutes; it can be completely dissipated by a mental effort, and can be reinduced by yielding to a relaxation, inducing a dreamy, pleasant mood. That is very evanescent. On substituting a small quantity of claret for the beer, the most careful intra-inspection cannot detect a trace of the psychological action of its alcohol. I know others on whom a single glass of beer has the same effect, or still greater, paralysing not only the vaso-motor nerves, as seen in the flushed face, but also the voluntary nerves, in loss of co-ordinating power over the movements of the tongue, and their speech betrayeth them. Where can be drawn here the line of demarcation? Does the glass of beer cross the limit of moderation, and the glass of claret fall short of it? Again, in order to arrive at an accurate estimate of the injurious or beneficial effects of the moderate use of alcohol, it is necessary to take into account the resisting power of the human system to noxious influence—the amount of toleration of which it is susceptible—the wide range of temperature from the Arctic region to the Tropics which it can bear with impunity; the miasmatic exhalation, so deadly under certain circumstances, yet when an individual becomes

acclimatised, he passes through these as if he possessed a charmed life. The dissection wound that might prove fatal to a young student from blood-poisoning proves harmless to one who has become habituated to the atmosphere of the dissecting-room.

The opium-eater and the laudanum-drinker swallow doses that would be lethal to others; and some of us remember the deadly sickness that crept over us as we were first trying the effects of that wonderful Virginian weed which afterwards came to exert such a soothing influence, when in the silence of twilight's contemplative hour we have mused in a sorrowful mood.

A solution of the problem we are seeking is for this threefold reason rendered impossible—there is no standard of health, there is no measure of moderation, and there is no possibility of correctly estimating the resisting power of the human system to noxious drugs. It is thus placed outside the region of demonstration, and all that we can hope to do is to oscillate and circulate as near the centre of truth on this point without the knowledge of when we have arrived exactly at it.

On the 3rd of July last Dr. Thomas Lauder Brunton, Lecturer on Materia Medica in St. Bartholomew's Hospital, gave evidence before the Committee of the House of Lords, appointed to inquire into the subject of intemperance.

In reply to query 9,249, Dr. Brunton stated that alcohol in small doses, when swallowed, somewhat increases the secretion of the stomach, and thereby aids digestion; it is then absorbed; it increases the heart's action, dilates the vessels, determines the blood to the surface, and gives a feeling of pleasant warmth and comfort.

In answer to 9,529, he says:—If a man eats well and sleeps well he does not require alcohol, he is better without it.

9,527. If a man is perfectly healthy he does not require spirits or wine; but if he is weak they are useful. If a man is working hard all day his stomach is exhausted like the rest of his body, and incapable of digestion; whereas if he takes a glass of wine first it begins to secrete the gastric juice, and his food is digested comfortably, otherwise it lies undigested.

9,356. Do you consider it equally necessary in case of great mental exertion? Yes.

9,357. I think even more so!!

9,365. Spirits taken during exposure to cold are bad, but after the exposure is over they are beneficial.

Dr. John Burdon Sanderson:—9,383. It was generally entertained some years ago that alcohol was not oxidised in the system. This has been completely refuted by very careful experiments.

9,384. An ordinary man may take as much as two ounces in twenty-four hours of alcohol, and the whole of it will be oxidised.

9,385. It is perfectly clear that alcohol does not go to build up any tissue in the body; on the other hand, it is

equally clear that it is used for the purpose of respiration. As long then as alcohol is taken in such quantities that it can be completely burnt, then it is beneficial; but as soon as it begins to accumulate it becomes otherwise than beneficial.

9,386. Alcohol cannot, like fat, be stored up in the system, but the question remains open whether it may not be converted into other kinds of force.

9,398. My belief is that upon the whole the human race would be situated as favourably if the use of alcohol did not exist.

I think so for two reasons. In the first place, because the evils certainly preponderate over the benefits; and the other consideration is simply that all the benefits are dispensable benefits.

9,406. Treating alcohol as a kind of food, there is no other food which deteriorates the organs, almost of necessity, in its use; but perhaps you do not admit that alcohol does so? I quite admit that.

9,435. You would say that the amount of pleasure which is given and the amount of medical aid which is derived from alcohol are overbalanced by the disadvantages? I do not desire to be understood as saying that it is desirable that the human race should do without alcohol even in health, for it is clearly beneficial.

There are two actions of alcohol on the health—that feeling of glow and increased comfort which it produces, which is a most desirable thing; and secondly, its exhilarating effect—its direct effect upon the nervous system.

On the 13th July last Sir William Gull gave the following evidence:—

9,993. I think there are conditions of the system under fatigue and exhaustion where alcohol might be useful, but I very much doubt whether there are not some sorts of food which might very well take its place.

9,996. Take the case of a man of twenty-five, sound in wind, and limb, and health, would you advise him to give up alcohol, if he were to ask you the question?

I think I should consider his calling. If he were a carter, or a man occupied out of doors much, I am not sure that I would not advise him to take some beer, but I am not very positive about it.

10,005. Many people believe that intellectual work cannot be half so well done without wine or alcohol? There I join issue at once.

10,007. Would you hold the very opposite? I should hold the opposite.

10,008. Would you say that a moderately temperate person might be benefited by a slight use of wine or alcohol? I should hold the opposite as regards the intellect.

10,009. The constant use of alcohol, even in a moderate measure, may injure the nervous tissues? Yes, certainly.

10,004. I think that taking it as a whole there is a good deal of injury done to the health by the habitual

use of wine and alcohol, even in so-called moderate quantities.

10,032. I think I have stated that alcohol in its various forms has uses, but I think those uses are very much limited by the age and health of the consumer. I think for the most part good food will supply all the wants up to the middle period of life; in old age and disease you may want some artificial stimulus. I would also say I do not know how alcohol does act upon the body altogether, but in disease it is very much as a sedative.

I have thus endeavoured to give what information the greatest lights, the most brilliant luminaries of British medical science, were able to lay before the highest court of inquiry in this kingdom, and I cannot say they have added very much to our knowledge—indeed their very greatness seems as if it would lead to bewilder, and their very brilliancy but dazzles to blind, and leaves us still wandering in darkness and in gloom groping after truth, if happily we may find it. Let us try and find out, if possible, the secret of the power it exerts over so many millions of mankind; this lies not in its effects upon the stomach in aiding or assisting the process of digestion, nor in any tonic or strengthening influence it may exert upon the system generally. It is the change it produces on the nervous system in which the magic of its power lies, and which renders its potency for good or for evil so enormous.

I remember in my boyhood of a neighbour who, though a little man, had at all times a knowledge of his own importance, but on market-days, on his return home, that sense of his importance had been considerably increased; he would strut up and down, stating that he was cock-of-the-walk, and woe betide any unlucky individual who dared to dispute his statement. I suppose to have a very exalted idea of one's self may be pleasant, and, perhaps, beneficial, but it rendered him very ridiculous in the eyes of all his acquaintances. I knew another who, when struggling with difficulties, and when a bill was falling due which he found it difficult to meet, he would go home, get a bottle of whiskey, and go to bed; he was enabled thus to forget all about his bill, though for the time being he was as rich as Rothschild, built no end of castles in the air, and only awoke from his pleasant hallucination to find the bill protested, his credit gone, and his commercial ruin complete. That it can impart a glow of pleasure and of comfort; that it possesses the power in some temperaments of inducing oblivion of depressing circumstances, and evolving those of a pleasing and exciting character; that it imparts courage and energy, enabling some individuals to do what otherwise they would not, could not, and dare not do, cannot, I think, be disputed. If you can define anything to be beneficial which adds to the pleasure and well-being of an individual, without any counteracting effects, either immediate or remote, then I cannot conceive how any one can deny that thousands are daily enjoying a pleasure, and, con-

Ulster Medical Society
Session 1877–1878
President George Frederick Wales

sequently, deriving a benefit from consuming a variety of drinks which contain alcohol. Whence then the terrible effects of drunkenness which lie around us? There are constitutions to which a small dose (how small I am not prepared to say) acts as a spark does to gunpowder, and leads to explosion. They cannot drink without getting drunk. I meet many of this type; they continue perfectly sober for months, perhaps without tasting a drop, but directly they take a glass, it is all up with them, and they never stop till the prison-cell arrest them, or sink into some other pit, till they can sink no lower.

Another class drink moderately daily, but take periodical attacks of drunkenness in which they commit the most disgraceful excesses, causing desolation and ruin if engaged in business, and bringing shame and disgrace and sorrow on their families. They awake with the most dreadful horror and bitter remorse, but only to repeat, after a time, the same sad cycle of events. I have known a few of whom it could not be said they were sober for years. They were constantly drinking, and the system thoroughly saturated with it. Even in such a state a considerable degree of intelligence, and even of commercial sharpness, remained. In these individuals the nervous system seemed to possess a marvellous power of resistance, and the destruction which inevitably comes, comes through the vascular system and secreting glands.

A most important question arises—are we in any way, however, unconsciously or unwillingly contributing to swell the list of drunkards? I have often heard this charge brought against medical men, and have hitherto set it down to that tendency to make excuse and throw the blame on others which has existed ever since the first sin was committed, and the first excuse offered. “The woman she gave me, and I did eat;” but recently cases have come under my notice where I cannot doubt the truth of the assertion, that the medical directions with regard to stimulants were the first step in a downward career to ruin, little dreamt of by those who prescribed them.

I look upon anæsthetics as one of the greatest boons that has ever been conferred upon suffering humanity, enabling us to wrap a patient in a gentle slumber, and carry him through the most terrible moments of existence without disturbing his tranquil sleep. These benefits have been dearly paid for, and many a valuable life has been the forfeit, but the benefits derived have been worth them all. Is it so with the administration of stimulants; do we derive benefits and advantages at all equivalent to the evils which follow, and to the risk and danger in which we place our patients. Have we any means of distinguishing beforehand the peculiar idiosyncrasy of an individual, that lays him at the feet of his passions, when once alcohol has been prescribed for him—or can it only be discovered when the fatal step has been taken, and when the mischief is past recall? I thought it would contribute materially to our know-

ledge on this point to procure, from one of intelligence and education, an account of the steps by which she was led to abandon home, and friends, and comforts, and all that we hold dear in life, for the spell and the charm that circles round the “cup:”—

Dear Sir,—Agreeable to your request, I will try to state how the degrading besetment I am now reaping the reward of first became a habit. I feel recalling these reminiscences rather more painful than I anticipated, and would gladly give it up but that I prayerfully hope it may benefit some, and also help myself to persevere in my determination never again to be the slave of such a vice—but to the point.

Up to the age of forty I had been a Sabbath school teacher, a tract distributor, and, as I thought, a Christian. Then came the testing-point. My dear father was taken from us; we had to leave the house that had been our home in infancy, and, although left in comfortable circumstances, I could not from the heart say, “Thy will be done.” I had a serious illness, reduced almost to a skeleton; the doctor, when I was recovering, ordered me port wine; I took it for a short time, but it produced such an unpleasant hot sensation in the head and face that I was advised to try a tablespoonful of brandy in water. This I soon tired of, as I always associated the taste of brandy with castor oil. Would to God it had ended there; but a dear good old lady, a friend of ours, told me to substitute whiskey—that was the fatal step. At first I thought it nauseous, but imperceptibly I began to wish it was the time to take it. I would not acknowledge this even to myself for a time, but gradually I began to increase the quantity, then to take it oftener, flattering myself that I needed it for some ailment or other. Oh! the sophistries of the human heart, when it wants to cherish any darling sin. After I had given way, and taken the subtle poison to excess, I persuaded myself it was all for the best, for had I not taken it at that time I should certainly have lost my reason, and so things went on growing worse and worse.

Never can I forget the first day I knew it had been noticed on me, and commented on. I tremble now when I recall the feeling of degradation and self-reproach, and how all the meanness and deception I had hitherto used to obtain it rushed to my mind, overwhelming me; but all this, instead of deterring me from ever looking at it again, only urged me on to get more to stifle the bitter anguish. Will you believe me, sir, when I tell you that I loathe the sin of drunkenness more than any other, and did at the time I was taking it? Mine has been one of the worst cases; I could not think I was taking it as a stimulant to elevate, but as a necessary sedative to quiet the irritation of the nerves.

Oh I when I look back, I wonder how I could so blindly deceive myself, and now feel, while writing this, what if it should ever occur again. You who have never known its power can never tell or know what it is to be

its slave—better, far better, a thousand deaths—but oh! I must claim deep, deep sympathy for all its victims.”

I thought the above statement from one sensitive, educated, and refined, would give us a deeper impression of the dangers that may hang around our directions than any words of mine could do. I trust that from this discussion some prophylactic measures may be devised, and some remedial ones suggested for that large and unhappy class who are suffering from one of the most hopeless of maladies.

If there be a gushing wound that calls for staunching—if there is a bitter wail of anguish and of agony that ought to be heard—if there be an imploring prayer for mercy and for pity that should be listened to, it is ascending from those who have loved-ones and dear ones that they would give their heart's blood to redeem from the most degrading of bondages, but they are helpless without your aid. Are they to be told that liberty is too sacred to be interfered with, and freedom an inalienable right? The only reply that can be given to such a statement is—O liberty, freedom, religion, what wrongs are being done in thy name.

It being nine o'clock, the President suggested that Dr. Cuming be not called to address them till next night.

Dr. Whitla proposed that the meeting should be adjourned until the following Tuesday night.

Dr. Dill suggested, seeing the session so well inaugurated, that in place of having the meetings fortnightly, they should be in future held weekly.

Dr. Cuming said this would necessitate a change in the rules, but there could be no objection to adjourning the meeting.

Dr. Browne seconded the motion of Dr. Whitla, which was passed unanimously.

The proceedings were then adjourned accordingly.

George F. Wales

Second Meeting December 11th 1877

Present, Dr. Wales (President), Professor Dill, Cuming, John Moore, MacCormac, Beck snr, McKee, Dempsey, Fagan, Spedding, Strahan, Lindsay, O'Malley, Clements, O'Neill, Coates, Jefferson, David Johnston, Esler, Wadsworth, Whitla, Speer, and about 20 students.

Dr. Esler moved the resolution referring to the journals lying on the table for one week previous to circulation be rescinded. Dr. Spedding seconded.

Dr. MacCormac moved as an amendment that the journals be allowed to remain a few days on the table. Dr. Moore seconded this.

The amendment was put and lost, and the motion of Dr. Esler was carried by a majority of 10 to 7. The original resolution of last session was consequently rescinded.

A ballot was taken and the following gentlemen were

elected members (each unanimously): Dr. Jefferson, Dr. Lindsay, Dr. O'Neill, Dr. Clements.

Dr. Spedding moved and Dr. Dill seconded the nomination of Dr. Wadsworth.

The adjointed debate on alcohol was taken up. Drs. Cuming and Dill took part and the time of the meeting having expired it was resolved to adjourn until this night week.

Paper:¹ Dr. Cuming, in opening the discussion, said:—The first thing he should be obliged to ask them was to restrict the discussion to the terms of the query. The terms had been selected with a great deal of judgment by the Council of the Society. The subject was one on which the members of the Society might be fairly asked to give their opinion, and outside that they ought not to travel. The terms were—“The moderate use of Alcohol—is it injurious or beneficial?” In the first place that clearly excluded altogether the question of intemperance, and left it as a matter perfectly foreign to the essence of the subject, and he was specially anxious that they should leave this out of consideration, because it introduced an element so much debated by the public, involving so many moral considerations, and on which the feelings of many were so strongly excited, that it would be very difficult to prevent their judgment being influenced in one way or other.

He thought that they should devote their investigations mainly, if not exclusively, to what the influence of the moderate use of alcohol was on the average human being in civilised life, and that they ought not to attach too much importance to merely exceptional cases—for instance, those individuals who had such a passion for alcohol that they could not restrain themselves from excess if they once tasted it at all. Nor need they dwell on those exceptional instances in which a small amount of alcohol produced a very great effect on the nervous system. These might be looked on as the idiosyncrasies, and had to be treated as exceptions, such as occurred in the use of morphia or mercury. In dealing with the broad general fact, they should examine it on physiological grounds, as they would examine how castor oil purged or chloral produced sleep.

In addressing an audience such as that before him, one might fairly assume that all the principal experimental evidence was tolerably familiar to them. They need not argue about theoretical considerations. The great question was—what was their own experience, their own observation as medical men? They were all agreed, firstly, that intemperance was a thoroughly bad thing. He was sure they were all agreed that a person might preserve the highest amount of physical health without taking any alcohol at all. That had been demonstrated so very fully by temperance societies, no one could doubt it. Then came the main question—was alcohol in moderate quantities useful? He knew when

¹ [Dublin Journal of Medical Science, 1878, v65, p253.]

he was entering on this subject, and undertook to discuss it at all, that he was touching on dangerous ground, but he felt that it was in a sort of way a duty he owed to the profession not to hide his own views. Now what were the conclusions that his own experience had led him to. He took the average man as he found him in his practice amongst the mercantile and professional classes, whose duties entailed a great deal of wear and tear, a good deal of expenditure of energy, and frequently considerable physical as well as mental exertion. What he believed he had observed in these was, that the use of a small amount of alcohol taken at the evening meal did the following things:—In the first place, it gave a certain amount of appetite to men whose appetite was occasionally doubtful, capricious, and possibly deficient. Again, he thought it sharpened the appetite of men when it was flagging; and, thirdly, he thought that it prevented or diminished the unpleasant sensation of fulness after eating, which was very common in those classes. He was speaking in this matter of averages. He knew there were many exceptions, many men who did very well without alcohol, but he spoke of the general run of men. Persons who were very much opposed to the use of alcohol in any form might meet this by admitting that alcohol can produce these effects, and following it by the statement that the effect passes off soon, and that there ensues a reaction which is equivalent to the primary stimulating effect. It might be said that it was quite true that there was an apparently beneficial effect at the time, but that that effect passed off, and that the patient sunk as far as he had been elevated—

As high as we have mounted in delight,
In our dejection do we sink as low,

This, in his own opinion, was not the fact. He thought that a small amount of alcohol did not lead to any injurious reaction. The question then arose—what was moderation in alcohol; was it possible to lay down a rule for moderation? and Dr. Moore had dwelt on this subject with a great deal of force, and urged that the difficulties in the way were such that it was not possible. It was difficult to lay down any rule, and impossible to lay down a strict rule; but there was no more real difficulty in making an approximation as to what was a quantity of alcohol than there was in ascertaining what was moderation in eating. If a person took such an amount of alcohol as in any way trammelled his mental or physical energy, or produced an uncomfortable effect on his sensations, or if he took an amount, beyond what he found others to use with safety or advantage, then he knew that he had passed the standard of moderation, and, he thought, that that standard should be fixed at a very moderate amount.

He believed alcohol did more than this. He thought a small amount taken by the average human being living in a high state of civilisation had the effect of blunting his susceptibility to petty annoyances. It had something

of an anæsthetic property. He thought it also to be to many a source of harmless gratification, and he did not think the pleasures of life were so very numerous that they should altogether ignore a consideration of this kind. Having gone over this part of the subject he must meet another objection made by total abstainers—that was, they would admit that these beneficial effects might be produced, but then they said the amount that would produce them to-day would not do so to-morrow or months hence; that they were on the edge of an incline; that in a year or so the quantity had to be increased, and so on until it went beyond the limits of moderation, and into the regions of intemperance. Undoubtedly this was a fact in many instances, but these instances he thought also to be exceptional; and, after looking over and very carefully considering this point, he thought from the observations he was enabled to make amongst the men he had known, and with whose history and habits he was familiar, that such a quantity as was taken for a beneficial effect did not require any addition whatever; and he thought that, so far from an increase being necessary in that way, the answer he would be inclined to give was that the experience of humanity was that rather a diminution was the rule than the exception. They saw many instances of this on a large scale on the Continent of Europe, especially amongst the French, Spanish, and Portuguese and Italians.

In these countries the inhabitants were accustomed to take a moderate amount of stimulants all their lives, and they were noted for being generally temperate. Whilst he was quite clear with regard to these views as generally applicable, still it had to be borne in mind that there was a considerable portion of the human race who were gifted with such special nervous organisations that the use of alcohol with them was attended with greater risk than with the generality of the community. Those who were subject to the complex nervous sympathies which were grouped together as hysterical manifestations seemed more liable to the injurious effects of alcohol than their more fortunately circumstanced neighbours, while they were less benefited by it.

He had only to allude finally to the position of the profession with regard to a question of this kind. All of them would recognise what enormous evils had been produced by intemperance, what misery and penury, how fertile a source it was of crime, of vice, and of physical degradation. They must be obliged to admit all this, but did that alter the physiological effect of small quantities. He did not think they should be influenced in arriving at a conclusion by considerations of this kind. They had to hold by scientific truth no matter what was the result. There seemed to be in the minds of many a fear that if they admitted any benefit from the moderate use of alcohol they were opening the door to intemperance and its evils. He was not sure that there was not some element of truth in this, and his sympa-

thies went with those who advocated total abstinence. His judgment and experience were on the opposite side. When they were asked by a patient would a moderate amount of alcohol be beneficial or injurious to him, he thought they should give a candid answer, without taking into consideration what influence his example might have on his neighbours, or what were the evils of intemperance in the world.

PROFESSOR DILL, M.D., after stating that he would not confine himself to the rules laid down by Dr. Cum-
ing, which he thought hampered discussion, said:—In arguing this question, I am disposed to lay it down as a principle—for at least my own guidance—that Science and our first great Authority are never found antagonistic to each other; and starting, as I do, upon this principle, we shall see how it may be brought to bear upon the question at issue, in its social, its moral, and its therapeutical aspects. If what has been stated be admitted, then I go further and assert, that as the use of fermented liquor is sanctioned and recognised for the use of man, we cannot step in to condemn the legitimate and temperate use of it, unless it may be on the ground of expediency. This being so, it must be admitted that it is the abuse and not the use—moderate use—of this agent which is to be discouraged.

I would, moreover, from a social standpoint, be inclined to say that, except where individuals offend against society or against self, or are in any way disposed to so offend, the law should not be put in motion.

I have been at all times an advocate of the very moderate use of alcoholic drinks, and I would still hold by the same opinion. But when I see the daily abuse of it becoming such a plague-spot on our society, then I am forced to the conviction that a reform is urgently needed. On this point I do not enter into details, neither is it necessary that I should here be more specific.

I have said that the question is a vexed one, and it is made more so by the discrepancies and the discordant views entertained by scientific investigators, and amongst medical men themselves. We have Dr. B. Ward Richardson publishing his popular tracts and delivering lectures upon the subject to the general community, sowing broadcast the seeds of his psychological dogmas, and inoculating the untrained mind in science with his fallacious arguments. I shall only take leave to say here, that there is evidence enough in his own statements for a satisfactory reply, and I believe that his whole argument applies to the abuse, and not to the use of alcoholic drinks.

Give me leave to offer you a specimen of Dr. Richardson's reasoning. He says that because the lower animals refuse the use of alcohol, ergo, it is not food; it is not suited to man, and should be rejected by him. As well might I advance as an argument the fact that, because my horse refuses to eat cabbage, ergo, cabbage is not food; it is evident that this animal cannot look upon this article as a favourite cordial. But we have as an

offset to Dr. Richardson's theory on this subject, the opinion of one of the ablest of scientific investigators—I mean Dr. Burdon Sanderson, who maintains that alcohol is a food, and may be used as such in moderation. My own experience leads me to the same conclusion, and that it is to be considered, under certain circumstances, as assisting in promoting recovery from disease. I have now passed through many a phase of life and medical thought, and some very extreme opinions on different subjects have been advanced and practised, and again more moderate views appeared to receive greater favour. I more particularly allude to the extreme views entertained at one time in regard to both the excessive use of stimulants as recommended by the late Dr. Todd, and the very free use of the lancet. These two extreme views are only known to history, and still the question recurs to us, "What of a little wine for the stomach's sake and for our oft infirmities?" to which I would reply, that I have no more right to condemn the general and moderate use of wine, than I have to condemn the proper use of bread and butter and beef.

He went on to say:—I have come to the conclusion that the stimulating plan of treating certain diseases is not so necessary as some would have us to believe. I am also of opinion that the symptoms requiring its use are not watched for with sufficient care, which symptoms are clearly told to us by Dr. Stokes—viz., when the heart's action begins to show signs of failure. The late Dr. Graves has handed down to us an expression of opinion in these words, that "he fed fever;" and, I have no doubt that to many, simple though these words may appear, they are too freely and literally interpreted.

I have in my own person experienced the disadvantage of taking brandy while making a long journey on the top of a coach, on a cold winter night, in the extreme fatigue felt next day. I made the return journey a couple of nights afterwards, on which occasion I took nothing of the kind, and I was comparatively free from fatigue on the next day. I have found that from half a glass to a glass of spirits will arrest the pains of labour as effectually as will two or three grains of opium. I have found that drinking habits are occasionally associated with disease of the womb, but I have not discovered whether it is the disease creates the habit for the drink, or the drink brings on disease.

I am also of opinion that drink creates an increased sexual desire; and do we not know that the poor "unfortunate," by her indulgence in alcoholic drink (as is usually the case), gets into a condition both of obesity and barrenness. I have often been surprised at the very great quantity of drink that some persons will venture to take—a pint, a quart, two quarts of whiskey, are no uncommon allowance over the day.

One would think that the words in the Spectator, by Addison, were applied as a delicate satire on the drinking habits of the age—"I am well, I would be better, and here I am."

Ah ! sir, I have often wished to see some fair hand of genius arise which would restore these matters to their proper level, for when in our highest degrees of enjoyment and happiness, are we not cast down to the lowest depths of depression, as we contemplate the sorrow and the suffering which that demon by his excessive use of drink has entailed, reducing this fair earth of ours to another Pandemonium.

The discussion was then adjourned until Tuesday, December 18th.

George F. Wales

The Third Meeting of the Society (adjourned) was held in the Pathological Museum on Tuesday December 18th 1877.

Present, Dr. Wales (President), Dr. Wheeler, MacCormac, Dill, Cuming, Beck Snr, John Moore, Coates, Spedding, Esler, Core, Dempsey, Strahan, Clements, O'Neill, Jefferson, Speer, D. Johnston, Whitla, and a large attendance of students.

Dr. Wadsworth was elected unanimously a member of the Society.

The adjourned debate on alcohol was for the third time taken up and the following gentleman took part: Dr. MacCormac, Beck Snr, and Dr. Wheeler.

Paper:¹ The debate was re-opened by Dr. Henry MacCormac, Consulting Physician to the Royal Hospital, who said:—The common sense and experience of mankind have long since decided the question as to the moderate use of alcohol. The properties of alcoholic drinks were known from the period—and that is now a long time ago—when the first man or woman laid aside for a little the pressed juice of the grape. Alcoholic drinks, without any reasonable doubt or question, are among the immense gifts of God, and when used with proper restraint and measure, are, or may be, productive of great good. This premised, I must now say that the abuse of alcoholic drinks was, and is, the source of prodigious evil. In fact the community are unaware of the ethics and physiology of fermented drinks, and would require very careful training in regard of both. There are multitudes, we must regret to find, who do not look upon alcoholic drinks as a source of partial sustenance and refreshment, but merely as one of animal enjoyment. The man or the woman who drinks with the express object of intoxicating himself or herself must be considered, in this respect, at least, as little better than a brute.

There are at the present moment some 150,000 public-houses in Great Britain and Ireland—all of them potential, and very often real, arenas of destruction and death. In these houses, men, and even women, spend the proceeds of their industry, robbing their families, debarring themselves of proper food and clothing and lodging, wasting their health and strength and

time, and rendering a provision for age, or illness, or accident, simply impossible. It could not well be otherwise when we find that £147,000,000 sterling are yearly paid across the counter for alcoholic drinks. The present earnings of the United Kingdom amount, it is said, to £1,200,000,000 annually. And were these earnings not so great, it would be impossible for British energy, prodigious as it is, to withstand so immense a drain.

As it is, there are a million or so of paupers—paupers reduced, in too many instances, to pauperism by excess and the almost utter absence of needful forecast. The gaols are filled with criminals, asylums for the insane with mad men and mad women, hospitals and the houses of the poor with preventable disease, more or less springing from the same cause. It is infinitely to be regretted that the fiscal arrangements of the country are such as to render it needful, or seemingly needful to derive a revenue, or at least so great a revenue, from the sale of intoxicating drinks. Would it not be better to tax property, or resort to other means to compass the requisite funds? Instead of holding out virtual boons for intoxication, every possible incentive should be yielded to the cultivation of habits of prudence, sobriety, industry, and forecast.

Compulsory education should be rigidly enforced all over the three kingdoms as well as in the colonies. Primary, intermediate, and technical schools, with lending libraries, should everywhere abound.

The Legislature, if it would, might, so to speak, put down intoxication in a day, for it has the power. Seventy or eighty years ago claret cost some £12 the hogshead—the price at which it may be purchased now. Then a war tax was levied, and the duty on imported wines raised to the monstrous amount of five shillings and upwards per gallon. Then began the introduction of brandied wines, and heady, unwholesome beer. The employment of such beverages, coupled too often with the habitual use of spirits, raw or haply diluted, instead of light wines and mild ales, has proved most disastrous. People unable to afford the one were content to rasp their palates with the other, and all the evils of intoxication followed in their train.

The mild light wines and pleasant beers of France and Germany, so harmless and refreshing, do not contain—the former more than from seven to eight, the latter from thirteen to fourteen per cent, of alcohol; whereas, not to speak of fiery ales and heavy porter, sherry, port, Madeira, and Marsala are so dosed with brandy as to contain thirty, and even upwards, percent, of alcohol. These alcoholic wines and heavy ales are really quite unfit for general safe consumption, since they are calculated, in too many instances, to lead to intoxication and disease—cannot, in fact, be largely partaken of without danger to sobriety and every prudential economic check. The employment of raw spirits, so very much resorted to by masses of the population—I

¹ [Dublin Journal of Medical Science, 1878, v65, p258.]

am sorry to add, of both sexes—is a pernicious, not to say savage, addiction. The natural, unbranded light wines of France, Hungary, and Germany, when unadulterated—say half a pint, a little more or less, at a meal—are absolutely uninjurious. I cannot speak too highly of Bavarian beer, and the light unintoxicating ales, generally, of Germany, Holland, and, indeed, those of France. They may be consumed in moderation by those who like them, with perfect safety, and I could earnestly wish to see them at the home table of the working man, and, as a support, to the nursing mother. In other respects fermented drinks of any kind should commonly be alone employed at mealtime. A prohibitory tax ought to be levied on brandy, whiskey, gin, and rum, whereas the duty on light Continental wines, unbranded, should be lowered from a shilling to a penny or two per gallon, with commensurate abatement in the malt and hop tax.

The half-pint of rum allowed daily, per head, in ships of war, should be changed for a half-pint of claret. The captains and officers do not drink rum, and I do not see why the men should. It only leads to evil habits. The German mode of brewing beer I would everywhere enforce by law. Sophistication of all kinds should be carefully guarded against. Municipalities should keep the public-houses in their own hands, and pay a fixed salary to the salesman, as is done at Gottenberg. These measures, if carried out by the Government in the first instance, and municipalities under them, would go far, I submit, to abate the ravages of intemperance, and render the moderate use of the great good gifts of the Divine Creator innocuous absolutely.

Dr. John W. Beck addressed the meeting as follows:—This question would appear, *prima facie*, a very simple one, and one of very easy solution. That the use, and particularly the moderate use, of anything which all mankind have been in the habit of using, when they could procure it, must have been in some sense beneficial, would appear to be almost self-evident. Indeed, this universal consent would seem to indicate that it was beneficial in all senses, and not at all injurious. But the question is not so simple as this. It is surrounded with difficulties. In starting for a conclusion we meet with so many modifying circumstances and disturbing elements, each of which must be taken into account, and each of which is so difficult to estimate as to its value, that we feel almost inclined to despair of being able to come at anything like a correct answer to the general question.

The answer, in any individual case is not so difficult, as the data for a correct conclusion are not only fewer in number, but much easier to be correctly ascertained. Still it requires great consideration, and will tax the skill of the best of us in any case. The first thing that meets us in this inquiry is the great difference in the opinions which have been formed, with regard to alcohol itself, by persons claiming to be experts. We find

soi-disant very high authorities setting it down as a “deadly poison”—whatever that may mean—compounded in Pandemonium: pronouncing, *ex cathedrâ*, everything connected with it, at all times, in any quantities, and under all circumstances as evil, and only evil.

Others, not so noisy, but I would say, with all due deference, of at least equal authority, have pronounced it to be a food, or at least a condiment, or both. It has been set down both as a stimulant and as a sedative. On the one hand it has been accused of causing degeneration and destruction of the tissues; on the other hand it has been extolled as one of the best means we possess of preventing waste of tissue, such as occurs in fevers and phthisis, or after long and violent exercise; and this, not only by inducing sound sleep, and thus putting the nervous centres into the best condition for recovering their own exhausted energies, restoring tonicity to the muscles, and vigour to the whole system, but also by supplying material for combustion in the lungs, and thus saving some more valuable hydrocarbon. I ask why do we find this wide difference of opinion among men equally in search of truth, and we must suppose equally capable of finding it?

Notwithstanding this—not too charitable supposition—I suspect the solution of the difficulty lies in the fact that alcohol is all these things, and produces all these effects, and a great deal more besides. Hence the difficulty of dealing with its use in health as a general question. To come more immediately to the question before us—the first point to determine is, what is the moderate use of alcohol? Can this question be answered with any degree of accuracy? If we cannot come at the truth, let us endeavour, in the language of my eloquent friend who opened this debate, to vibrate or oscillate as near it as possible. I conceive that in proportion to the correctness of the answer we can give to this question will be the value of any conclusion we may come to in the matter.

It is universally known that what would be a very moderate quantity of alcohol for one individual would be quite an immoderate quantity for another. The glass of punch that might be necessary, of an afternoon, to make an octogenarian feel comfortable, help him to digest his dinner, and procure for him a good night's sleep, may be quite sufficient to make a younger man not only very uncomfortable in the evening, but rise with a very sore head in the morning. I cannot at all agree with Professor Cuming that the quantity of alcohol which the average man—idiosyncrasies apart—may imbibe with safety, or benefit in the twenty-four hours, is anything like as easily to be ascertained as the amount of beefsteak that the average man ought to eat, with good effect, in the same period of time. Any maitre d'hôtel will be able to tell to an ounce how much beefsteak a given number of the average man will consume in a given time; but will at once pronounce the alcohol

Ulster Medical Society
Session 1877–1878
President George Frederick Wales

they will imbibe in the same period of time to be an unknown quantity. I told a gentleman a few weeks since to abstain from alcohol altogether while under my treatment. A week or two afterwards he volunteered the remark that he had abided strictly by my orders in everything, and had been particularly abstemious, not having exceeded three or four glasses each day since he had come under my hands. I give you this as a sample of what some people call, not only moderation, but abstemiousness. But, to come nearer our subject. It has been stated, and I believe correctly, that the system of an ordinary healthy adult could digest, use up, dispose of, or eliminate if you like, about two ounces of alcohol in the twenty-four hours without any trace of injury being left behind.

So far, I think, there seems to be no controversy; but, was it beneficial? Well, if it added to the feeling of comfort of body, and contentment of mind, and left no sting behind, I should say it was—even supposing the process was only elimination, pure and simple. But there is something more to be considered than this. Does this daily dose, of two ounces of alcohol, entail no mischief? It is admitted, on all hands, that during its operation it lightens the burdens of life, gives a brightness to the intellect, an elasticity to the step, and paints the whole world *couleur de rose*. This seems a very desirable state to be in, but can it be made to continue indefinitely, or even for any considerable length of time? The experience of us all at once answers that it cannot.

This unusual—I would say this unnatural—strain, action, energy, or whatever else you may choose to call it, cannot be maintained. The system gradually becomes accustomed to the two ounces of alcohol, and the world and its concerns come back, *pari passu*, to their old, common-place jog-trot. You will observe I am supposing the dose has not been increased. Now, the question arises—the question under debate—has this man, in the prime of life and health, gained or lost anything by thus daily dosing himself with two ounces of alcohol? He gained a little pleasure—gratification—for a short time, while the alcohol was new to the system, but that appears to be all. He could have done as well without it. He probably lost nothing, but he risked a temptation to increase the dose. Professor Cuming seems to think that this risk is very small, and that, in the majority of cases, the dose is not increased. It is very difficult to ascertain the truth in this matter; but this is contrary to all my experience. If the alcohol be now dropped altogether for a sufficient length of time, the same process may be repeated again with the same results. Unfortunately, this is very seldom the case. The attempt is generally made to retain and prolong these benefits—and benefits they certainly are, as far as they go—by increasing the dose; but such attempts must necessarily fail. The overexcitement of brain and the surcharge of alcohol which follow this course are sure to bring about a fearful retribution. How few there are comparatively who

having habituated themselves to this daily dose of two ounces of alcohol stop there. I have known several, however, who, having palpably lost any benefits they had obtained from this daily dose, and wisely fearing the temptation drawing them to increase the dose, dropped it altogether. I know several gentlemen who, with the snows of time descending on their heads, abstain altogether from touching alcohol, though for twenty or thirty years of the prime of their lives they indulged in their daily dose without ever exceeding it; and they dropped alcohol for these reasons. Now, this I would call reversing the order of nature. They used—not abused, remark—alcohol when it was little, if any, use to them, and they now abstain from it when it is calculated to be of much value in their declining days; and the more valuable it would be now had they refrained from it in earlier life, but I confess I would be very slow in advising them to touch it again.

And now I will say a word on the abuse of, or rather, on the temptation to abuse, alcohol. It is a long time since the wisest of men said, “Wine is a mocker.” It is a mocker. How many have unwisely increased, and continued to increase the dose, till, taken in an unknown quantity, it not only ceased to be a pleasure, but became an absolute necessity for the very existence of their beastly nature. Nay, none can know better than my present audience of a nature reduced far below the level of the beast that perishes. It is melancholy to reflect how many (some of them the finest specimens of men—aye, and the loveliest of women too) have fallen before this unknown quantity, which, at first, in their judgment, constituted “the moderate use” of alcohol; but, once over the boundary of the really moderate use, the rest is easily told: *facilis descensus*.

Gentlemen, we are the advisers of men. They look to us for guidance in this matter; and they too often look to us merely to sanction a “use” of alcohol, which they are perfectly conscious is a thorough abuse of it. How difficult it is for a medical man, placed in these circumstances, to act conscientiously, we all know. But here we must be, to a great extent, our brothers’ keepers. Let us ask ourselves, *Quis custodiet custodes?* or, should I not rather say, *custodiret?* It becomes a serious question with us, medical men, whether the beneficial effects of alcohol, such as they are, do not sink into utter insignificance when weighed against the injurious effects produced by the temptation—the amazingly strong temptation—to increase the dose up to the unknown quantity that leads to complete destruction.

For my own part, I do not believe alcohol to be either necessary or beneficial in healthy adult life, under ordinary circumstances—say from puberty up to fifty, and, in some cases, sixty years of age; and I am quite convinced, from experience, that females are much more liable to be injured by it than males during this period of life. I need scarcely touch on the use of alcohol in infancy; for, after a practice among infants of more

than forty years, I have no hesitation in saying it can be of no use there, but must in every case and under all circumstances do harm. During youth and up to puberty, we are, perhaps, on more debatable ground; but I hold much the same opinion of alcohol during that period as in infancy—let it alone.

We now come to what I consider the real use of alcohol in health. After fifty or sixty years of age “the moderate use” of alcohol will do no harm, and may do a great amount of good. If judiciously used, its dietetic use in the last decade of life’s years may be very valuable, and it will be found to be much more valuable, as I have before hinted, in declining years, if it has neither been used nor abused in early or mature life. Besides, I hold that the temptation to increase the dose injuriously in any individual who has scarcely touched it at all till after fifty or sixty years of age, is about nil.

This is no mean consideration to anyone entering on life. In proportion as they refrain from alcohol in early or mature years, in like proportion will they not only reap all the benefits its use is capable of conferring on their declining years, but in like proportion will they also escape from its evils. (Dr. Beck then related an instance where he had treated a patient, an old lady of about ninety years of age, who had been a consistent abstainer during life. Some weeks since she had an attack of diarrhoea, and after trying, first, wine, and then whiskey, neither of which had the desired effect, he suggested bitter ale, the use of which soon produced a marked change on her health and appearance. He said he had no doubt the lady owed the prolongation of her days to alcohol, presented to the stomach in the shape most agreeable to it, and most fit to be digested by it under the circumstances.)

In conclusion, he said:—Notwithstanding all that can be said, and truly said against alcohol, I never could see the way clear enough to become so much of a Turk as to eschew alcohol altogether. I have no fault to find either with those who entrench themselves behind the Kara Lom of “Teetotalism,” or of those who fortify themselves in the Plevna of “Good Templarism”—but I altogether dissent from the conduct of those enthusiastic Turks who will persevere in breaking their heads against the impassable Shipka Pass of that craze called “The Bible Wine Question.” Gentlemen, he is a wise man who, in health, can let alcohol alone; but, in my opinion, he is a much wiser man who can touch it moderately, and gently, and carefully, without being seduced by it to injure either his health, or his pocket, or his character.

Dr. Spedding moved and Dr. Cuming seconded the adjournment of the debate till Wednesday 2nd January.

G. F. Wales

Session 1877–78.

The Fourth Meeting of the Society was held in the

Museum on Wednesday evening January 2nd 1878.

The President (Dr. Wales) in the chair. Present Drs. Aickin and J. W. Browne (Vice-Presidents), Dr. Dill, John Moore, Harkin, Dempsey, McKee, Wadsworth, Esler, Jefferson, Strahan, O’Neill, Dr. Wheeler, Dr. Speer, Core, Whitla, and a considerable number of students.

Drs. Esler, Aickin, Whitla, and Speer took part in debate.

Paper:¹ DR. WHEELER gave a history of alcohol and its preparations in every known form, quoting from the Sacred Record, and from Herodotus and Homer, to show its effects on body and mind. He condemned the use of alcoholic fluids as beverages, on the grounds that they were not only unnecessary in health, but positively injurious, and from long experience and patient observation endorsed fully the statement, “that he who drinks will drink again, and that moderation (with many) oils the hinges of the gate leading to excess.”

He quoted from a very able paper of Dr. Wilks, physician to Guy’s Hospital, and also from Dr. Parkes’s paper on the use of a spirit ration in the Ashantee Campaign, which proved that alcohol is not a stimulant, nor a trustworthy aid. He also quoted the opinion of Dr. Parkes and other well-known workers, who agree that the use of alcohol in health is in no way beneficial, but on the contrary, in many instances, decidedly injurious, by exhausting the vital powers and inducing disease. He finished by saying it was needless to dilate upon the dangers which surrounded the use of it as a beverage, and believing that moderation so frequently leads to intemperate habits, thought that they, as medical men, should be very careful that in no way they should encourage the drinking habits of the age.

DR. ESLER said:—Mr. President, the limits put to this discussion by the very terms of the proposition makes it so narrow that one is almost forbidden to touch upon the moral, the social, or the therapeutic aspect of the question.

In thinking this subject over, and in listening to the many speakers who have preceded me, I am driven to the conclusion that the issue arising from the first proposition is too narrow, and for this reason—that you take a standard of health as the condition requiring to be benefited.

Now health—that is, good health, cannot be improved upon, and unless alcohol be proved to be food, and a harmless food, even a desirable food—and until it be shown that an increase of the heart’s action, that is, of the work done by the heart, is not in any degree hurtful to the animal economy—I, for one, fail to see that it is beneficial in health; besides tens of thousands of healthy men with practical experience, and a vast array of the best names in the medical profession, all testify that alcohol in health is unnecessary.

¹ [Dublin Journal of Medical Science, 1878, v65, p360.]

Recently a correspondent of some eminence in *The Lancet* tried to show that in his case a small quantity of alcohol daily was necessary to maintain good health and digestion, detailing three different occasions on which he had given it up, and on each occasion his tongue furred and his appetite failed. My reading of the case was, that this eminent member of the profession had acquired an artificial taste or habit, by which the peptic glands were stimulated to pour out their secretions, and without which they would not act well. Perhaps a little more perseverance would have overcome the difficulty. Against this case I do not think it would be difficult to quote a number where the use, even the moderate use of alcohol, has produced results exactly similar to that produced in this case from abstinence, and the lesson I would draw from it is one for youth—viz., not to acquire the habit, for habit, any habit, and especially the drinking customs of society are too strong to be easily thrown off.

The second aspect of the question is put thus, “Is the moderate use of alcohol injurious?” The answer to which need not turn on the definition of the word moderate. That its immoderate use is injurious no one will question.

Alcohol injurious? Yes. And alcohol in moderation injurious? Yes, and for these reasons:—It fosters an artificial state of appetite, digestion, existence: it is always a dangerous boundary line on which to walk, and immoderate and injurious are moderation’s nearest neighbours; it is a bad example to the young, and to others who have not full self-control. This, to medical men, is an important element in weighing the question, as none of us dare venture to ask, “Am I my brother’s keeper?” That is our trust, whether we answer the question or no.

It is an expensive habit, and this to a great many people is injurious enough. Many a man’s pocket-money spent in beer, and many a woman’s pin-money spent in gin, leaves the fire small on the hearth, the bed-covers thin, cold, and comfortless, and the children’s boots leaking at every point. Remember, too, that its estimated cost to this nation alone is nearly a hundred and fifty million sovereigns in gold.

We have heard a good deal in this discussion about light wines, as if light wines were to bring in a reign of moderation, and it has been affirmed that there is little excess in wine-growing countries. Sir, history and experience have written on the very forefront of wine—DANGEROUS. I am sorry I have not Continental experience, like some of my predecessors on this question, but I have been over a large extent of the wine-growing districts of Victoria, and I can testify to the old experience that it is not uncommon to err through wine, “to err in vision and stumble in judgment.” I have been assured by those who have practical knowledge of the whole question from their residence in grape-growing districts, that the most chronic form of tippling, and

one of the most insidious, is that induced by the constant use of wine; and, leaving out of account the gouty diathesis to which it may lead, I am not inclined, with my present information, to subscribe to the doctrine that light wine is the antidote required to stem the ever-widening torrent which has already devastated, and which threatens yet more extensively to destroy the medical, the social, the industrial, and the moral relations of society. I rather subscribe to the old statement, “Wine is a mocker.”

In conclusion, sir, if I say that, as a therapeutic agent, I consider alcohol almost invaluable—certainly indispensable—but that in health, especially the health of youth, I do not think it is necessary; that it is only exceptionally beneficial, and generally hurtful, and that it is injurious in a degree proportionate to the quantity taken; that its use, when indulged in as a luxury, should be in extreme moderation, only with food, and not habitually, you have pretty much my opinion on this whole subject.

Dr. Speer said:—Mr. President and Gentlemen, I shall briefly state my views on this question thus:—

1. That in my humble opinion the moderate use of alcohol in health is positively injurious.
2. That in cases where its use is decidedly beneficial, the person using it is not in a state of perfect health, in which instance it is fairly entitled to be regarded as a medicine, not a food.
3. That a comparison physically of total abstainers and moderate drinkers would tell immensely in favour of the former; so would a comparison on the question of healthiness.
4. That it is a fact proved to the satisfaction of every honest mind that total abstainers can endure greater cold and more excessive toil than moderate drinkers; and I submit that this fact is a telling argument against the moderate use of, or necessity for, alcohol in health.

Dr. Aickin, Vice-President, said:—Mr. President, the question of alcoholic stimulants being necessary or unnecessary in health, seems to suggest a preliminary inquiry—namely, what do we understand by the term health? It appears to be that nice balance between waste and repair of tissue, which the use of ordinary food produces in our bodies. When this state of fair balance exists, we might say the health of the individual is “at par.” In this we include the healthy action of the nerve-power as kept in the state of natural excitomotor action, by the natural stimulus of healthy blood circulating through the cerebro-spinal system; this cerebro-spinal system in its turn acts upon the whole circulatory system, forcing every separate portion of it to perform its office, whether at the heart or at the ultimate capillaries of each organ or part of the body, giving it that power which removes effete matter, and appropriating from the passing current of blood what is best suited for replenishing the particular tissue

through which it is circulating. This takes place I say when the strength (nerve power) is at par. If this is the state of things in a healthy body, produced by ordinary food, as evidenced by millions of the human race who have never used alcoholic stimulants, then I say alcoholic stimulants are not necessary to maintain a healthy person in health. Contrariwise it will be easy to show, by following the preceding arguments, that their influence on health is generally hurtful. Why? because the nerve-power is overstimulated. When this is done, the immediate effect is to produce—1st, a too rapid action of the heart, sending blood too quickly through the body, preventing the capillaries taking nutriment deliberately and sufficiently. 2ndly, the effete matter is removed too rapidly, congesting the organs that should eliminate this matter, being for the time overtaxed, and not able to act so hurriedly, being over-burdened. 3rdly, this congestive state is further increased, as we know that after excessive stimulation the strength sinks proportionately as far below par as it was stimulated above it.

The effect of this lowered state of capillary circulation is a subsidence of nerve-power below health, producing accumulation of effete matter in capillaries, which means poisoning, requiring a fresh impetus by means of stimulation to get rid of the deposited matter, which if permitted to accumulate will ultimately destroy health, and healthy action of part affected, so that we find that continued stimulation requires, through use and abuse, continued but steady increase to produce the same effect, until ultimately the excitomotor power is so overtaxed that it is impossible for it to respond to the stimulus, and so breaks down through sheer fatigue and want of time for natural resuscitation by nutritious food. This is what takes place when the strength is forced "above par." Now comes the question—when are alcoholic stimulants necessary? Answer, when the strength is "below par." This is constantly the effect when disease has produced that amount of debility which requires stimulation. It then in part raises the functions of the different organs up to par, producing stimulation of nervous system, then increased action of heart and capillary system, giving it power to remove effete accumulations, and by its preservative influence preventing too rapid decay of tissue, as constantly takes place in disease; it also stimulates digestion, directly and indirectly (by nervous influence), and also, by its narcotic property, acts as a soothing agent to the then irritable nervous condition produced by disease. From the foregoing reasoning I consider alcoholic stimulants necessary when strength is below par, or in debility after disease; unnecessary when strength is at par; that their influence is generally hurtful in health, and positively injurious when strength is pushed above par.

Dr. WHITLA (Hon. Sec.) said:—Mr. President and Gentlemen, it never occurred to me to speak upon this subject,

nor should I even now, but for your informing me that it was your intention to call upon me in this meeting. You want an expression of opinion from men who have spent years in the practice of their profession, and the value of the opinion upon a subject like this is certainly in proportion to the donor's experience. Being one of the junior members of the Society, I would consider it wholly unpardonable if I occupied your time at any length. I had not taken alcohol for twenty years, but after hearing and reading much about its beneficial results, I determined to try its effects upon myself. For a period of two years I took small doses of alcohol daily, with more or less regularity, believing now that its use was highly beneficial, and now that it was as lowly pernicious; and it was not till I had repeatedly ceased, and as often resumed it, that I felt at all satisfied with the result.

I found that, in addition to the temporary glow of comfort, dilatation of the superficial capillaries, cutaneous insensibility, cerebral activity, &c., one effect was markedly constant, and as this is the most important of the effects produced by small doses of alcohol in health, and as time is short, I purpose to attentively look into it. I refer to the increase of appetite. Those who opened the debate, and who seemed favourable to moderate doses of alcohol in health, have given prominence to this action. Dr. Cuming, who so ably laid down that the groove in which the discussion should run was that of health, immediately proceeded to say that alcohol in moderate doses will give an appetite to a man who has none.

Now, is a man without an appetite a fit subject to illustrate the physiological effects of alcohol? Here, I believe, lies our most important and vital issue; and without attempting to define "health," I think, sir, in considering these resolutions, if we would keep in our mind's eye a typically healthy man, who is to be just at the time of our experiment in the condition of perfect health of mind as well as of body, much of the difference of opinion on this matter would vanish, and we could hardly conceive any one unable to say that to such a one alcohol is necessary. I found that when in health, the consumption of food was always increased at that meal with which it was taken; this is generally admitted, but in my case I found that the total amount consumed in twenty-four hours was diminished. This is too often overlooked; we order small doses of alcohol with dinner to a patient whose appetite is lagging, and we find he eats more, but there is often no benefit. What are we doing? Compelling a stomach to do an amount of work in an hour and a half which should be spread over twenty-four. In such cases alcohol is manifestly injurious. I believe that all men with vigorous appetites eat much more than is necessary for the maintenance of the organism, and this surplus acts as a direct stimulant to the nerve, vase-motor, muscular, and digestive systems, and produces effects identical

Ulster Medical Society
Session 1877–1878
President George Frederick Wales

with small doses of alcohol. During the two years trial of alcohol I was weighed about every eight weeks, and only once was there any marked increase in weight; and I was much surprised, and still am, that this increase followed a period of total abstinence from alcohol, having entirely suspended it from the time of being weighed till next. This is the more remarkable when we consider that the form of alcohol was strong ale.

Well, Mr. President, to sum up my little experimental experience of alcohol, I must say that experience has led me to entirely discard it when in health, which I have done some months ago, and has brought me irresistibly to the conclusions so ably expressed by yourself to the Council, viz.:—

1. That alcoholic stimulants are unnecessary in health.
2. That their influence on health is only exceptionally beneficial.
3. That their influence on health is generally hurtful.
4. In order to lessen the hurtful consequences attending the use of alcoholic stimulants, I believe that, if used, they should be in extreme moderation—only with food, not before dinner, and not habitually.

I cannot sit down without referring to a few statements made by one who so ably spoke at the commencement of this debate. Dr. Cuming no little surprised me when he stated “that in order to daily experience the physiological effects of alcohol, it was not necessary to increase the dose, but if anything to diminish it.” This is not my experience, and if it were true as a rule, I believe there never would have been the necessity for this Society discussing for four nights the sad question of alcohol. To those whose appetites are good, but who wish to be “throned over petty annoyances,” I cannot recommend its use, or call it “an innocent gratification,” knowing by what an awful train of woe this gratification is often followed; and the fact of our being physicians does not release us from the terrible responsibility of being our brothers’ keepers.

The PRESIDENT then read the following resolutions of the Council of the Society:—

“The Society considers,

- “1. That alcoholic stimulants are unnecessary in health.
- “2. That their influence on health is only exceptionally beneficial.
- “3. That their influence on health is generally hurtful.
- “4. In order to lessen the hurtful consequences attending the use of alcoholic stimulants, the Society advises that, if used, they should be in extreme moderation, only with food, not before dinner, and not habitually.”

To the first resolution Dr. Dill moved, and Dr. Dempsey seconded, an amendment, “That the Society considers the use of alcoholic stimulants are not generally necessary in health.” The amendment was put to the meeting and lost.

The resolution “That the Society considers that alcoholic stimulants are unnecessary in health” being put to the meeting, was carried.

The second and fourth resolutions were withdrawn.

The third, “That their influence on health is generally hurtful,” was carried by acclamation.

The President then made the following remarks:—We have now reached the conclusion of the debate on “Alcohol: is its moderate use in health beneficial or injurious?” and, after full and free discussion, we have decided by a majority of votes that it is unnecessary and generally hurtful.

I think we owe much to our senior and leading brethren for coming out and giving us so freely of their valuable experience on this important question, which, I am sure, will be read with interest and profit by all to whom the promotion of temperance is a matter of concern, and I consider it highly satisfactory that members generally, and more particularly my junior brethren, have declared themselves so emphatically on what I regard as the correct side in its scientific aspect, but which, beyond doubt, is the safe side.

I would not have it understood that I condemn the occasional moderate use of alcohol in any form in health, or say that it necessarily does harm, but I do condemn and fear the daily habit of using it even in strict moderation, because a want is thereby created, on the regular supply of which comfortable feeling largely depends; and when a healthy man finds his happiness in any degree involved by his not swallowing a certain amount of alcohol daily, his independence is already largely compromised, and he is liable to be enslaved by the most seductive, tyrannical, and dangerous of all influences; for it must be remembered that it is out of the habitual, and at first moderate, taking of stimulants that excesses grow, and victims are made. How many these are may be assumed by considering the amount of money spent by the people of these kingdoms annually in the purchase of intoxicants—£147,000,000!

Enough in little over five years to pay off the national debt; enough, if spent in supplying food, clothing, domestic requirements, and otherwise beneficially, to develop good trade, the physical, mental, and moral well-being of the people, national greatness, and general prosperity—an average of £23 a year for each family! or nearly £5 for each man, woman, and child! And what do the people get in exchange for all this expenditure? Misery, misfortune, disease, crime!

Your vote this night must have considerable influence in awaking many to a sense of incipient danger. It is a most unselfish vote, for, next to the revenue and the publicans, who benefit so much as we by the intemperance that prevails? It is a vote I look on with great satisfaction, as the first act of the Ulster Medical Society in my year of office, and it is one, gentlemen, which I feel well assured we will never have cause to regret.

Dr. DILL moved, and Dr. Wheeler seconded, a vote of thanks to the President for his conduct in the chair during the debate, which was passed by acclamation, and which brought the meeting to a close.

Dr. McKee proposed and Dr. Whitla seconded the nomination of Dr. Anderson

G. F. Wales

The Fifth Meeting of the Society was held on Tuesday January 15th in the Museum.

Present, Dr. Wales (President), Professors Cuming and Dill, Drs. Wheeler, Esler, Gribbin, Coates, J. Moore, Speer, Lindsay, Clements, Graham, Strahan, and Whitla.

A ballot was taken and Dr. Anderson was unanimously elected a member of the Society.

Dr. Dill in a suitable speech proposed and Dr. Wheeler seconded the following:

“Resolved That it is with feelings of unfeigned sorrow we have heard of and are this day called upon to record the death of Dr. William Stokes of Dublin, Honorary member of this Society, whose great loss will be long and deeply felt not only by every member but by the profession at large and by the whole community as that of a man of whom it may be justly said, and in the truest sense of the words, that he was a perfect gentleman, an accomplished scholar, a great teacher, and an able physician.”

The Secretary was directed to forward a copy of the above to his son.

Dr. Whitla (Honorary Secretary) showed the liver and gallbladder of a patient who died from jaundice by obstruction.

Paper:¹ Dr. Whitla showed the liver and gall bladder of a patient, aged seventy, who had died of jaundice, and gave a brief history of the case. The jaundice had lasted, as far as could be determined, three months and a half; the patient was insane; and, when first coming under observation, a large tumour was detected in the right hypochondriac and epigastric regions. The question of its being an accumulation of fæces or a malignant growth was weighed, and it was determined to try the effects of a series of enemata. To this the patient rigorously objected, and it was found impossible to inject anything into the colon. Laxatives and ol. ricini were ordered, but she refused all medicines; once a little jalap was administered in wine; the patient detected it, and could never be again induced to take it.

Three weeks before death diarrhœa set in—the evacuations resembling fluid tar—and she gradually sank.

On opening the abdomen, the colon was found filled with hard scybalæ—a large accumulation being found at its right bend; its walls were thickened and opaque, a low form of inflammation having extended through its

coats, the gall bladder was full; the cystic duct was almost closed, and near its junction with the hepatic was much narrowed; the lower part of the choledoch duct was normal, a large mass in the colon having by its pressure almost entirely closed the biliary canal near the junction of the cystic and hepatic ducts to form the ductus communis choledochus; a trace of bile was found in the small intestines. The other organs were healthy, except the kidneys, which were congested, but otherwise unaltered.

DR. SPEER remarked that the structure of the liver was apparently natural, and asked had it been examined by the microscope.

DR. GRIBBON had seen several cases where impaction of fæces had produced diarrhœa. He, however, had generally noticed that some scybalæ had come away in the motions, the nature of which he often found resembled those described in the case before them.

Dr. DILL objected to the term diarrhœa being used in a case where there was impaction of the fæces. The word dysentery should be used when describing a case of this sort, especially where it was evident that there were very considerable quantities of blood in the motions. He had himself found ipecacuanha useful, and believed, had it been tried here, good results would have followed.

Dr. WALES thought the specimen very interesting. As regarded the symptoms during life, the presence of jaundice and diarrhœa were especially liable to mislead. He thought that the exhaustive discharge from the bowels in one so advanced in years was quite sufficient of itself to cause death. Probably, as had been said, death was owing to a variety of causes.

He also exhibited the uterus and ovaries removed after death, the uterus being filled with small fibroid tumours and the ovary being cystic.

Paper:¹ DR. WHITLA exhibited the uterus and ovary removed from a patient after death. He thought of showing the specimen, which he obtained the day before, not because there was anything remarkable in the cystic degeneration which was present in the ovary, but he thought it interesting as Dr. Cuming was about to relate to them a case of rupture of the ovary which had caused death in a young patient.

The cyst before them was not larger than a pigeon's egg; it was a purple colour, owing to the flattening out of one or two veins which occupied its surface; the contents were clear and transparent; the walls were of such tenuity that apparently a very slight blow over the abdomen would cause its rupture. It gave rise to no symptoms during life. The uterus to which it was attached presented some very unusual features. It had studded in its walls about a dozen small fibroid

¹ [Dublin Journal of Medical Science, 1878, v65, p450.]

¹ [Dublin Journal of Medical Science, 1878, v65, p451.]

tumours; two near the fundus were sub-peritoneal; this accounted for the shotty feel of the organ. The tumours were hard, about the size of large hemp-seed (one was larger than a cherry-stone), and were distinctly encapsuled, shooting out of their bed upon a slight incision being made over them. From the roof of the uterus hung a small polypus into its cavity. The uterus was removed from an old virgin of seventy-four years.

Dr. WHEELER thought the length of the neck of the uterus was remarkable. The organ would not weigh two ounces, and it seemed to be all made up of cervix. With the tumours, which he thought were fibro-muscular, he would have expected some hypertrophy instead of atrophy.

Dr. DILL thought the uterus, considering its source, was normal in size and weight, and was not more atrophied than the age of the patient would lead him to expect. While recognising the polypoid nature of the small internal tumour, he would be suspicious of the schirrous character of the isolated growths through the uterus; but, not having examined them microscopically, he could not speak positively. He would suggest their being carefully examined, and perhaps cancer cells would be found.

He also exhibited the liver of a patient who had died of hepatic fatty degeneration and Dr. Wheeler gave the history of the case.

Paper:¹ Dr. WHITLA showed a section of a liver, removed the previous day. It presented, in a well-marked degree, all the characters of the fatty degeneration. The cells were broken down, and filled with granules and oil globules, the field being obscured with debris of cells in all stages of transformation, from normal to oil globules. There being some interesting points in the history of the case, he would ask Dr. Wheeler, under whose care the patient had been, to mention them. The entire organ would weigh, he thought, between 6 or 7 pounds.

Dr. WHEELER said the case was to him a very interesting one, especially as regarded the symptoms—viz., violent and agonising attacks resembling angina pectoris; the pain being referred first to the region of the heart, and afterwards over the abdomen in its upper part. These attacks became more and more frequent, and the patient sank in a typhoid condition. The enlarged liver could be felt during life, but it was not clear whether its enlargement was owing to one of the degenerations or to cancer. A large tumour had been ligatured in the rectum about two years previously, the nature of which at the time he believed was hæmorrhoidal or polypoid, though a distinguished surgeon who saw it thought it was malignant. This always threw a doubt in his mind when thinking over the probable nature of the tumour in the hypochondriac

region. In the gall bladder was found a large gall stone, which he thought caused the attacks of pain. The examination was made under difficulties; and he regretted the heart was not examined, the chest being unopened. The patient was never jaundiced. All the abdominal organs were healthy.

Dr. Cuming showed a drawing and gave a complete history of a case where death followed a rupture of the ovary in a young woman.

After a lengthened conversation upon the above specimens, it was agreed as the usual time of the meeting had transpired that Dr. Esler should read his paper next night.

George F. Wales

The Sixth Meeting of the Society was held in the Museum of the Hospital on Tuesday January 29th.

Present, Dr. Wales (President), Professor Dill, Dr. Harkin, McConnell, Lindsay, Graham, Jefferson, Dempsey, Esler, Spedding, Wadsworth.

Dr. Harkin exhibited a patient labouring of chronic psoriasis of many years standing treated by the local application of Chrysophanic acid with beneficial results.

Dr. Whitla also showed a patient upon whom he was trying the acid; on one side of the body.

Combined papers.¹ Dr. HARKIN gave the details of a patient's case who had suffered for nine years from psoriasis. He was a boy aged now about fourteen. He had been so completely covered with the eruption that he was unable to appear in school or be sent to any business. He narrated the various remedies which he had tried—arsenic, phosphorus, iron, &c., as well as nearly every known form of ointment. At the conclusion of each line of treatment he was found to be in much the same state as when he commenced. Hearing of chrysophanic acid, he determined giving it a trial. In three weeks after its use the skin was healthy, and no trace of the eruption was visible. The results were so remarkable that he thought it his duty to produce the patient before the Society.

Dr. Harkin then showed the boy, whom he had not examined for several months—i.e., since the cure by the acid—and it was apparent that there was some slight return of the disease, as a few spots were visible on the back of the chest, the skin elsewhere being entirely healthy.

Dr. WHITLA (Hon. Secretary) showed a patient who had been under his care for three months, and taken large doses of arsenic for a very extensive eruption of psoriasis, some of the patches on the body being as large as the palm of a man's hand. The arsenic had no effect whatever upon the eruption, which continued to increase. Hearing from Dr. Harkin of his success, he

¹ [Dublin Journal of Medical Science, 1878, v65, p452.]

¹ [Dublin Journal of Medical Science, 1878, v65, p453.]

commenced to try the chrysophanic acid, exactly seven days ago; and in order to satisfy himself about the result, the ointment was very carefully applied to one side of the body only. At no place had the application on the trunk extended across the middle line. The patient, a boy aged thirteen, then stripped, and a remarkable difference was observed between the two sides of the body resulting from the seven days' treatment. In no place was the eruption entirely removed, but it was evidently fast disappearing. He could not satisfy himself that mere friction with plain lard could produce any such marked effect, especially as tar ointment had been carefully applied before. He merely produced the patient to show the members the remedy in process of application, by way of illustrating Dr. Harkin's case. Attention was then drawn to the most unusual expression of the patient from the colouration of the skin round the eyes, which gave him the appearance of an owl; and he thought that this effect must be produced by the acid after its absorption. The bed-linen and clothes of the patient were destroyed by its staining properties.

PROFESSOR DILL thought the cases highly interesting to the profession. He had looked upon psoriasis as an opprobrium to the healing art, but the cases which he had seen before the Society encouraged him greatly, and if the cure remained permanent, he would say it was a great triumph. He had formerly believed it was a blood disease, but in those cases the local remedies seemed to have the most effect. Dr. Harkin's case, though after several months showing a tendency to return, he thought, was most remarkable. Did the acid act locally or through the blood? This, which he thought a most interesting point, seemed to be answered by Dr. Whitla's case, where there was a decided change on that side of the body to which it had been applied.

DR. MCCONNELL was not a believer in the chrysophanic acid. As far as he could see, he thought that psoriasis could be temporarily cured by almost any application, but invariably returned. He had produced results quite as satisfactory as in the cases shown, by a simple lotion covered with oil silk. In his own experience he had not met with any successes; in all the disease returned. He had no experience of the acid, but would try it in a case of twenty-five years standing, which he had under his care.

DR. ESLER was disappointed in Dr. Harkin giving no account of the history of the remedy. He detailed some particulars about its early introduction into Belfast. He agreed with Dr. McConnell, that nearly every application could be made to remove the scales, but the disease always returned. Hebra said psoriasis was incurable; if so, there was little use in chrysophanic acid.

DR. SPEDDING had much experience of the disease in the dispensary, but found it always returned. He thought more stress should be laid upon the constitutional treatment, as he believed it occurred generally in

strumous constitutions. He found much benefit from cod liver oil and iron.

DR. DEMPSEY thought the cases, upon the whole, very satisfactory, but thought Dr. Harkin's was showing signs of return.

The President, in reviewing the different theories about the pathology of psoriasis, and the alterations which knowledge of the disease had made in its treatment, was inclined to think most favourably about the success of chrysophanic acid treatment. He commented upon the published cases of Mr. Squire, to whom he thought great credit was owing. He hoped to see the cases brought before the Society again, at the expiration of a few months.

Dr. Esler read a paper upon the disposal of the dead.

MR. PRESIDENT,—The object of this paper is practical. The introduction I desire to make somewhat historical. The intimate connexion and the frequent contact of the medical man with that state called death may be considered a sufficient reason for taking a general survey, and at the same time for looking somewhat critically at this subject—a subject which, I am bound to say, is shunned rather than studied by the great mass of mankind—the only exception perhaps being that of the profession to which it is our privilege to belong. Ever since the patriarchal expression, “bury my dead out of my sight,” it has been the custom of all ages to give effect to the same feeling in some form or other. The ravages of decay and the decomposition of organic matter make it imperative that the dead body be disposed of in such a way as will at once satisfy the respect and affection of friends, and prevent the imperial laws of organic change in its alteration of living into dead matter becoming an offence, or sowing anew the seeds of contagion and death.

In the oldest history to which we have access we learn that the original method of disposal was interment, and it is a somewhat curious circumstance that since the days of Abraham we have not made much improvement, if any; and however for a time other methods have been adopted, civilised peoples, at least, have gone back to the old plan, and bury their dead; and even to the buying of the field and the possession of a freehold in “God's acre,” the Abrahamic spirit and independence is strong amongst us in this nineteenth century.

The method to which we are referring, and with which custom has made us familiar, is repulsive to the natural affection which binds mankind in families, and it is not difficult to conceive of a case in which strong feeling prompted a desire to retain the presence and outward form of some patriarchal father, heroic leader, or tender friend, and called forth the marvellous skill of the Eastern physician who introduced the process of embalming, for which Egypt must ever

stand so famous. But there are other and I believe the true reasons why embalming was adopted by the Egyptians, and that was to preserve the body as a receptacle for the soul, when according to their doctrines it should return to earth after having completed its cycle of *three*, or according to some of *ten* thousand years. The art was practised at least 2000 B.C. The record runs that "Joseph commanded his servants the physicians to embalm his father, and the physicians embalmed Israel."

The method adopted was this:—If a male, the corpse was at once committed to the undertaker's; if a female, it was retained at home till decomposition had set in.

There was an embalming officer of low class, whose premises were situated in the cemeteries. He was called the "Paraschistes," or flank incisor. His duty was to open a line on the left side below the ribs, which had been previously marked by a scribe. This he did with an Ethiopian stone or flint. He was then pelted with stones and pursued with curses. Another embalming officer then proceeded to remove the viscera, with the exception of the heart and kidneys; the brain was extracted by another embalmer by means of a crooked instrument through the nose. In this state the body was ready for future operations, which depended on the sum to be expended on the task.

Three methods prevailed. The first was practised only by the wealthy, and consisted in passing peculiar drugs through the nostrils into the skull. The abdomen was rinsed out with palm wine, filled with costly spices, and the wound stitched up. The mummy was then steeped in natron for seventy days, wrapped up in linen cemented with gum, and set upright in a wooden coffin against the side of the tomb. Herodotus mentions that the Ethiopians placed their mummies in glass coffins, but none of them have ever been discovered.

This process cost a silver talent, or about £725 of our money.

The second process was like the first in removing the brain. The viscera was injected with cedar oil, and the corpse soaked in a solution of natron for seventy days, which brought away the soft portions, and left only the skin and bones. This method cost a mina, value £243 English. The third method was for the poorer classes. The body was washed in myrrh and salted seventy days. The cost was only a trifle. One author states that a common cost of embalming was £108. The body was often kept at home and not sent to the cemeteries, and was produced occasionally at festive entertainments to recall to the guests the transient lot of humanity.

In the fifteenth and sixteenth centuries of the Christian era mummies were used for drugs and other medicinal purposes, as well as nostrums against disease.

In embalming, the Persians employed wax, and the Assyrians used honey. Alexander the Great was preserved in both wax and honey.

During the present century the discovery of the preservative powers of alumina, arsenic, zinc, and corrosive sublimate, enables the student of medicine to cheaply and simply embalm the body for a short period for anatomical purposes. The latest cases of embalming recorded are those of King Victor Emmanuel of Italy and Pope Pius IX.

In addition to burial and embalming, a third method, is *incremation*. This was practised and is still a custom in Eastern lands. It is the universal custom among the Hindoos. Their practice is for those who are rich enough to procure wood to make a funeral pile on the beach or river's bank. On this the corpse is placed. The heir or chief mourner, followed by a procession of relatives, walk round the mound seven times. When the leader applies his torch, all the followers in succession follow his example. Where the people are too poor to purchase wood, they provide cow manure, which is dried in the sun, and serves the purpose admirably. They do not preserve the ashes or put them into urns, but all is allowed to remain until blown away by the first wind, or washed by the rains into the surrounding sand or earth.

The body of Saul and also of his sons were burned, and it is supposed that in their case this method was adopted on account of the advanced state of decomposition of the corpses.

In Greece, in Etruria, and in the north of Europe, this method was practised simultaneously with burial. The tombs of these countries are said to be rich in art, much of it going to the adornment of the urns in which the ashes were deposited, and there can be little doubt that the urn as a decoration of our modern cemeteries is borrowed from this custom. The cineration of the body and the preservation of the ashes in urns is said to have come in with the bronze period, as previous to that the bodies were buried in stone coffins. Among the Jews the custom prevailed of having their sepulchres hewn out of the solid rock, the opening to which was enclosed by a circular stone running in a groove.

There is almost no subject so deeply interesting to the living as the thoughts and associations connected with the dead; and it has been remarked that there is nothing so distinctive of the character of a people as the way in which they dispose of their dead. Heathen or half-civilised people permit the remains of the dead to lie unburied or strewn about on the surface of the earth, and I am enabled to show you a sketch of the method in which the aboriginal tribes of Australia deposit the remains of their friends on a platform of branches out of the reach of the native dogs. They have not the implements of husbandry wherewith to dig a grave, and even if they had, I am inclined to

think they are too lazy to perform the rite. However, that is their mode of disposal.

The Parsees of India have enclosures built, called “towers of silence,” where they lay out their dead naked and exposed to vultures; and I have been told by a resident in India that he has passed by these towers of silence when on the lee side of the enclosure the vultures were congregated and luxuriating in the foul gases which emanated from within.

No civilised nation would allow their friends and scarcely their enemies, to remain unburied, and the greatest contempt with which an enemy can be treated is to meet the fate of Jehoiakim—“He shall be buried with the burial of an ass, drawn and cast forth beyond the gates.”

A notion has prevailed at all times that the dead might require some of those things in which they indulged in life, and so it has been a custom to put into the coffin various articles. The Chinese enclose tapers and slippers as needful helps in the flowery spirit land to which they are committing their dead. Another of their customs is to adorn their cemeteries with a profusion of tapers, which they light up after a funeral. The late notorious Mormon prophet, Brigham Young, was not quite sure of his bodily peace even after death, for he left express instructions in his will to leave him room in his coffin in which to turn.

The disposal of the dead at sea is made a necessity to prevent decomposition, otherwise there is a disposition, where at all practicable, to convey the dead to land; yet a sea burial is one of the least objectionable, and, indeed, in many respects the most desirable of all methods. There seems to be a fitness in committing the body, with its mysteries of resurrection, to the mysterious ocean, with its unfathomed bottom, far-reaching and unexplored shores; and there is no funeral solemnity comparable to that rite of committing earth to water.

A person while living has the power of disposing of the body after death, and I recently read of a case where an American lady left her body to her physician, asking him to honour his sanctum with her bones.

The expenses connected with death have always been very considerable—sometimes, indeed, enormous; and some of the grandest buildings in the world are monuments and tombs, of which the pyramids are a striking example.

Churches became burying places in this way:—If a church was dedicated to a saint, the bones of that saint were, if possible, deposited near the altar, and so great was the desire to be buried near these saints that men of piety or rank or riches obtained a burying-place in the churches. This practice became extended and originated churchyards.

As towns increased in population, the churchyards became overcrowded, and on sanitary principles

many of them have been closed up. The laws regulating burial date so late as 1853 for England and 1855 for Scotland.

In England the parishioners have a common law right to bury in the churchyard, but the body must not be interred in an iron coffin or vault.

To interrupt a clergyman in reading a burial service or to conspire to prevent burial is an indictable offence.

There used to be a popular notion that to permit a funeral to pass over private property constituted it a public right of way. Such an opinion is founded on error, but it is a privilege of persons going to or coming from a funeral to be exempted from toll. Persons found *felo de se* used to be buried at a cross-road corner with a stake through their body, but this barbarous mode was abolished in the reign of George IV., and the law directs that their bodies shall be buried without ignominy, privately in a churchyard, between the hours of nine and twelve o'clock at night.

While on the subject of burial, I cannot pass by burial societies without some notice, and that chiefly in the way of condemnation. The object is to provide money to pay for burial after death, and is confined to the lower classes. It often happens that paupers in the union are being paid for by friends outside who claim them when dead, and obtain the money on which to have a funeral carousal; but a worse feature is the insurance of infants, and in my duties in connexion with one of the charities of this town I am often painfully conscious of the burial money acting as a balm in no small degree to the bereft parents. From the judgments I have formed of the effect of the working of these societies, I am strongly of opinion that they should be discountenanced.

We have seen, in this necessarily brief survey of the practice of disposal of the dead, that *burial* is the custom among those who believe in a resurrection, and at present Christians, Jews, and Mahomedans adopt it. *Embalming* was practised by those whose faith led them to look for a return of the soul to earth, while *burning* and various other methods characterised those who had no definite creed on this important subject.

In coming now to the funeral rites and customs of disposal of the dead in Our own country, we find the forms varying with the faith of the deceased, the locality to which they belonged, and the rank of life in which they have moved.

On the Continent and in England the coffin is generally made of wood, covered with cloth, or sometimes of polished oak. This is borne in a hearse gloomily draped with nodding plumes and unmeaning carvings. This is followed by a number of mourning carriages, all drawn by black horses. In England it is not uncommon to see the hearse preceded by a class of undertaker's men, called “gumpheon men,” who are

Ulster Medical Society
Session 1877–1878
President George Frederick Wales

the bearers of a pole with a knot of crape on the top. These are supposed to clear the way. In Scotland the funeral ceremony is simple, and although the Scotch used to give expensive entertainments to the guests, the practice is becoming less observed every year.

Let us now see how things are done in the Emerald Isle. Most of us have seen an Irish wake—I mean a real country wake. When any one dies, the clock is stopped, or at least the striking weight is taken off, and the face covered with a clean white linen cloth, as is also the dresser, the table, and chest of drawers. There is a plentiful supply laid in to provide for several days, eating and drinking, with tobacco, whiskey, and clay pipes in abundance. The neighbours assemble after their work, and often sit the night through. All who smoke help themselves without let or hindrance, but the whiskey is disposed of in a somewhat different fashion. At regular intervals during the night there is a large brew of punch prepared by some one in charge of the hospitalities. This is distributed in doses estimated to be fit for full-grown persons, and in this way a wake extending over two or three nights becomes an expensive affair. On the morning of the funeral the whiskey bottle and biscuits are freely passed among the assembled friends. It is gratifying to know that in many districts these customs are rapidly disappearing, as from such habits scenes often arose which were anything but edifying. The practice pursued among the rich is different, and instead of sitting around the corpse in the fashion of a wake, the body is locked up over night, when the family retire to rest. It was this practice which enabled servants to dispose of the bodies of their late masters in the time of Burke and Hare, when the resurrection men were driven to adopt any device in order to obtain subjects for the dissecting rooms.

Black is the colour which is almost universally recognised as the proper expression of mourning, and crape as the material which most correctly suits the mourner. And at funerals, in some parts, there is a profusion of black crape worn, not only by the relatives but by their hangers-on, dependents, clergymen, and doctors. In the north of Ireland, and, indeed, in Ireland generally, both the colour and the material have been superseded—the colour being white and the material linen. So that white linen for shoulder-scarfs and hat-bands is the prevailing custom among us. This change is said to have been brought about in order to encourage the staple trade of Ulster, which is linen.

A practice has long prevailed among the landed aristocracy of giving perquisites to their dependents on the death of a member of the family. And on the death of a landlord, this sometimes takes the form of a new shirt, or the making of one, to every tenant, which is worn at the funeral as a shoulder-scarf; while all coachmen and cabdrivers are provided with the

making of a shirt-front, which is worn as a weeper round the hat.

Now, let us take one of our modern funerals, and what do we find? Perhaps, on the whole, the proportion of expenditure in connexion with sepulture is in keeping with the means at command; but, often, it is enormously beyond it. In our towns it is rare to find that the old practice of wakes, tobacco and whiskey, is looked upon as a necessary accompaniment of death. And among sensible people the practice of gratuities is disappearing, and we could wish this were entirely abolished, especially as the recipients include clergymen and members of the medical profession. Cabdrivers need not refuse weepers, as, indeed, I find them seldom refuse anything, unless it be their proper fare.

But why clergymen and doctors should be classed with cabmen, and singled out as the objects of gratuity in the material for a new shirt, has been to me somewhat puzzling. That the custom was introduced and has been continued in order to compensate clergymen who have been shamefully underpaid as a class, I do not doubt. And that doctors came in on the same plea, we may easily suppose. And, just lately, I have learned that it is a practice among a certain class of the population to give their clergymen an equivalent for a shoulder-scarf, estimated at three half-crowns, in which event an old scarf is worn at the funeral. And, at least, one medical man in Belfast has been offered, more than once, the money, in case he preferred it to the linen. He, however, declined to receive either. I have known of families being plunged deeply in debt as the result of extravagant funerals. Let the people in their lifetime add something to their pew-rent and give their minister's a fair support; and let them pay their doctors' fees in reasonable time; but let not a custom such as I have been describing be continued in our midst—for this is a custom which, I think, would be more honoured in the breach than in the observance. Because one happens to be the clergyman or the physician to a deceased person is no reason, in my opinion, why he should allow himself to be made a mute, a gumpheon man, or a walking advertisement through the crowded streets of a town, in order to cater to a love of vanity and display.

I have reason to believe that not a few medical men are dissatisfied with the present custom of wearing shoulder-scarfs. Were clergymen only to refuse to receive and hang them on their pulpits, and were this Society to pass a resolution, or even come to an understanding, that none of its members should receive or wear them, this remaining token of feudal times must speedily be banished from our midst, so that our dead might be buried in a decent, becoming, and unostentatious manner.

Thus far I have avoided the advocacy of any particular method of disposal of the dead, so that a concluding

line on this point may close this paper. Our faith will not permit us, in this country, ever to revert to the Egyptian custom of embalming; nor do we think it desirable even by the presence of the preserved body to recall to our own or the notice of others the transient state of humanity. The lesson is written all around us. Cremation will never do for Christendom, which is indoctrinated with the hope of a resurrection. Our faith and our firesides alike rebel at the idea. Heathen customs may do for heathen countries, but must ultimately yield to civilisation. Therefore, burial alone remains to be, as it is, practised in these lands. There is a fitness in committing "earth to earth," nor can we hinder it, if we would. I lately read of the stone coffin of one of the Saxon Kings being opened. His jewels, which were buried with him, were there unaltered and uninjured, but of the King there remained only a handful of dust.

The direction in which I should like to indicate a change would be, not in the better preservation of the body, but rather to dispense with vaults and coffins of stone, lead, or other strong material, and to adopt the method which has been advocated by Mr. Seymour Haden, in *The Times*, of making the shell of light material or wicker-work, ornamented, if you will, and made pleasant to the eye with flowers—fit emblem of man's sojourn here—so that we might not even try to hinder the great and immutable laws of Nature exercising their inalienable right to the legacy: "Dust thou art and unto dust shalt thou return."

After some discussion upon Dr. Esler's paper he gave notice that on following night he would move "That believing the custom of wearing shoulder scarves by medical men at funerals to be objectionable we resolve as far as we can to discountenance the practice".

The Secretary read the following letter which he had received from Mr. Stokes of Dublin:

5 Merrion Square N., Dublin
January 21st 1878

To W. Whitla, Esq. M.D.

Dear Sir, I am in receipt of your kind favour of the 18th inst enclosing a copy of a resolution adopted by the Ulster Medical Society at the last meeting. Will you convey to the members of your Society how deeply I feel their thoughtful kindness in sending me so signal a proof of the esteem in which they held my late father and assure them of my gratitude for their friendly sympathy.

I remain, Dear Sir, faithfully, W. Stokes
PS I have no objection whatever to the resolution being printed with your ordinary transactions.

G. F. Wales

The Seventh Meeting of the Society was held in the Museum of the Hospital on Tuesday February 12th

1878.

Present, Dr. Wales (President), Professor Dill, Drs. Wheeler, Gribbin, Moore, Graham, Coates, Esler, Speer, Core, Spedding, Dempsey, Whitla, Jefferson, McKeown.

Dr. Dill proposed, and Dr. Fagan seconded, the following resolution:—"That this Society, at its first meeting since the decease of Surgeon Henry M. Johnston, one of its oldest members and most esteemed ex-Presidents, desires to put on record its sense of loss by this sad event, and to express its sympathy with his relatives in their bereavement; and further, that the Honorary Secretary be requested to send a copy of this resolution to the Rev. Wm. Johnston, brother of the deceased."

Dr. Esler moved "That believing the custom of wearing shoulder scarves by medical men at funerals to be objectionable we resolve as far as we can to discountenance the practice". Dr. John Moore seconded this but objected to a paragraph being placed in the newspapers embodying the resolution.

Dr. Wheeler, though agreeing with the motion, did not see his way to have the Society move publicly in the matter. He strongly recommended the resolution to be withdrawn.

Professor Dill agreed with Dr. Wheeler.

Dr. McKeown spoke strongly against the habit of wearing shoulder scarves as degrading to the profession as it classed them with case-men and labourers.

Dr. Dill reminded Dr. McKeown that the scarf was always presented to medical men as badges of respect.

Dr. Spedding objected to the matter being taken up by the Society publicly. He thought that no steps should be taken till all the clergy of all the denominations should be asked to meet the Society.

Dr. Core supported the motion, pointing out the fact that these scarves were for display and if abolished would eventually prevent medical men being asked to attend funerals.

Dr. Speer agreed with the spirit of the motion.

Dr. Strahan expressed himself satisfied with the course of the Society interfering in the question.

Dr. Coates agreed with the motion but strongly dislike the idea of publishing.

Dr. Graham agreed with the motion. He thought the scarf was given for display and not through any respect to the profession.

Dr. Gribbin thought that the wearing of the scarf was not a mark of respect to the medical man but an advertisement that the patient had slipped out of his hand. He thought with Drs. Wheeler and Dill that it was hard to refuse the patient's friends. He thought the matter should be let drop. We have no power to interfere.

Dr. Wales' own personal feeling was that he should like to say that he personally objected and that he was

also at liberty to say that if he wore the scarf he did it under protest.

Dr. Spedding moved as an amendment that “We take no public action in the matter without first asking the clergy of the various denominations to confer with us in this matter, and if the conference approve of it that we act conjointly and advertise it in all the local papers”. This was seconded by Dr. Wheeler, put to the meeting and lost.

Dr. Dill after asking Dr. Esler to withdraw his motion proposed as an amendment “the previous question”. This was seconded by Dr. Wheeler, put to the meeting and lost.

Dr. McKeown moved as an amendment that the words “by medical men” should be struck out in Dr. Esler’s motion. This was put and lost.

Dr. Esler’s motion was then put and carried but no authority was given for the matter to be published in our newspapers.

Dr. Wales then open up the 2nd question on the paper, i.e. the retrenchment of expenditure. He regretted the absence of the Treasurer but laid the financial state of the Society before the meeting and urged them to consider the advisability of considering some method to cut down the expenditure.

After a long debate the recommendation of Council was read by the Secretary and Dr. Core moved and Dr. Jefferson seconded the dismissal of the messenger as the only way to cut down the expenditure. This was put to the meeting and carried, 8 for the motion and 3 against. It was decided the messenger should get 3 month’s notice.

Some conversation take place regarding the Library and it was agreed to refer the matter to Council for their report at next meeting.

G. F. Wales

Eighth Meeting February 26th 1878

Present, Dr. Wales (President), Drs. Fagan, Core, Coates, Dempsey, Esler, Jefferson, D. Johnson, and Whitla (Secretary).

The Council report on the Library question was entered upon and Dr. Core was requested to act as librarian which he kindly agreed to do. The question of remuneration to Captain Cox was fully entered into, also the statement of Council, and on the motion of Dr. Coates, seconded by Dr. Whitla, the meeting resolved to give £10 to Captain Cox for his services.

Dr. Core was unable to read his papers.

Dr. Fagan could not produce his patient.

George F. Wales

Ninth Meeting of the Society March 12th ‘78

Present, Dr. Wales, President, Drs. Dill, Esler, Dempsey, Speer, Lindsay, Fagan, Whitla.

Dr. Dill proposed and Dr. Fagan seconded the following resolution: “That this Society at its first meeting

since the death of Surgeon H. M. Johnston, one of the oldest members and most esteemed ex-president, desires to put on record its sense of loss by this sad event, and to express its sympathy with his relatives in their bereavement, and further that the Honorary Secretary be requested to send a copy of this resolution to the Rev. William Johnston, brother of the deceased”.

Dr. Fagan introduced a patient upon whom he performed the operation of sub-periosteal resection of the ulna.

Paper:¹ *Annie Reid, aged three years, was admitted under my care on the 17th November, to the Children’s Hospital. She was affected as follows:—Forearm much swollen—this was most marked at the ulnar border—and ceased abruptly about a quarter of an inch from the head of the ulna, and one inch from the top of the olecranon; the hand was puffy; there was great pain along the region of the ulna. The elbow and wrist-joints were quite free. There was a sinus discharging matter about one inch below the olecranon, and through this a probe passed down along the ulna as far as its head; the periosteum was separated from it in its whole extent.*

The mother stated that about ten days previous to admission she noticed that the arm was very painful when pulled out of the sleeve of the dress. She rubbed it with soap liniment; it became worse. She took her to a medical man who ordered a poultice. After some days an abscess burst over the olecranon, giving relief to the acute pains, and reducing the swelling.

After some days I made a free opening over the lower end of the ulna, so as to favour the discharge of matter and prevent burrowing about the joint. Gradually the swelling and acute inflammatory symptoms subsided, and on the 4th January, six weeks after admission, I removed the necrosed shaft, through an incision about an inch and a half long at the seat of the upper opening. The shaft was apparently quite loose, but, notwithstanding I used a considerable amount of force with a pair of strong sequestrum forceps, I was not able to remove it until I passed an elevator through both the upper and lower openings, and detached several bits of periosteum that remained adherent. I packed the cavity with some carbolised tow, and placed the limb on an angular splint. She made a good recovery. It is now a year and a half since I removed the bone; the ulna is quite restored; there is no deformity; and the only difference observed between the two arms is the presence of two small scars on the one that was affected.

Dr. Whitla showed a specimen [of] the forearm and hand, the seat of large recurrent fibro-nucleated growth; and exhibited under the microscope its structure.

¹ [Dublin Journal of Medical Science, 1878, v66, p262.]

Paper:¹ J. B., aged sixty, a strong, healthy man, sought advice for a small tumour situated below the styloid process of the radius, in the interval between the extensor *primi* and *secundi pollicis*, and extending internal, to this later tendon. It was as large as a hen's egg, and at parts gave the sensation of fluctuation. The skin was movable over the tumour. It looked at first sight like a large ganglion, for which it had been mistaken by two surgeons. It was of upwards of twenty years' growth, and latterly had been very painful, and interfered with the motion of the hand, which had become almost useless.

He willingly consented to its removal, which was accomplished easily in May, 1877—the tumour dissecting out from its connexions without any adhesions; it had dipped down beneath the tendons and lay upon the radial artery and external lateral ligament of the wrist, extending by a tailed end under the flexor tendons on the front of the joint. From this latter situation it was turned out by the handle of the scalpel. The tumour itself had a distinct fibrous capsule, and resembled a very large testicle in appearance. On cutting into it, it was seen to be made up of matter resembling in appearance and consistence foetal brain, with minute extravasations, causing blotches of cherry-red and darker colour through it.

Its microscopic characters were those generally seen in myeloid growths—giant cells enclosing many oval nucleolated nuclei, as well as free nuclei, and many caudate and spindle-shaped nucleated cells, like fibre cells. There were here and there throughout masses of filamentous tissue, resembling imperfectly fibrillated connective tissue in the foetal condition.

The tumour returned in the cicatrix about four months after its removal, and continued to rapidly increase in size. The patient sought the advice of an unqualified practitioner, who applied some local remedy, which caused extensive suppuration. In this state he again consulted me, worn out with pain and anxiety; and, having procured the assistance of Professor Gordon, I amputated the limb at about the middle of the humerus.

The beautiful dissection of the tumour, which I now show to the Society, was kindly made by Professor Redfern. Its attachments are deep, being adherent to the carpal bones; but the unusual and most remarkable point in the case seems to be the manner in which it has behaved towards neighbouring structures. At no spot, for example, could it be seen that the skin was infiltrated with the growth, though the two seemed intimately connected. They readily were separated by dissection. The tendons of the wrist and fingers showed similar anomalous relations. The common extensor of the fingers tunnelled through the centre of the mass unaffected, while one of the deeper tendons was lost in

it. The tendency of the tumour seemed to be to push the tissues aside, and, at the same time, its growth was so rapid as to almost convince one that it buried the surrounding tissues in itself, though at no place could real infiltration be shown; its microscopic characters were less definite. Cells—epitheloid in appearance—with bright nuclei, predominated, and many oval or rod-shaped nuclei were free. Bodies closely resembling the forms described by Dr. Bennett, as seen by him in the “fibro-nucleated tumour,” were present, and throughout were evidences of the same filamentous matrix as was seen in the first tumour. Taking the history and physiology of the tumour into consideration it had, doubtless, many characters of both the innocent and malignant growths, and seemed to belong to the debatable ground between.

Dr. Fagan thought the clinical history of the tumour very peculiar. Its recurrence after the first growth lasting twenty years, he believed, was unique. The naked-eye characters of the tumour would alone lead him to believe it was of malignant nature. He detailed the history of a case bearing on the one before the Society. From what he had seen of tumours, he believed the less we interfered with innocent growths the better, unless their removal was necessary for the proper exercise of the limbs upon which they grew, as in this case.

Dr. F. E. Beck concurred with Dr. Fagan. He thought, in this case, that the second removal was absolutely necessary.

Dr. Dempsey thought the speedy recurrence of the growth, after its first removal, was evidence of its malignant nature.

Dr. Wales thought the tumour a very interesting one. He did not believe that we were justified, in the present state of our knowledge, in denying the existence of an intermediate race of tumours between the malignant and innocent growths. He reviewed the history and characters of the tumours, and thought it did not belong to either class properly speaking. He commented upon the results of the last debate of the London Society upon cancer, and the uncertainty of many of our theories about the origin of carcinomatous growth. He believed there was nothing for this case but operation, and he thought there was a chance of its not returning.

Dr. Dill read a paper upon Version Versus Forceps.

Paper:¹ Professor Dill said—Mr. President, the paper which I have this night the honour of bringing under the notice of the Society is one of much interest, but it may be considered too comprehensive for such an occasion as the present. I shall, however, endeavour to reduce it to as narrow a limit as possible, or as may be consistent in discussing such an extensive subject as indicated by the notice of it in the circular—viz., “Ver-

¹ [Dublin Journal of Medical Science, 1878, v66, p329.]

¹ [Dublin Journal of Medical Science, 1878, v66, p335.]

sion versus Forceps: with notes on other operations suited to the different degrees of pelvic contractions, including Gastro-Elytrotomy and Ablation of the Uterus;" and, indeed, I may say that we should not be unprofitably occupied were we to continue the discussion of this very important and extensive subject over more than one meeting. Obstetric surgery is at all times an anxious department in practice, and it becomes more so when we find ourselves in the presence of a case surrounded with such difficulties and embarrassments as may raise doubts in the mind of the operator as to one operation or another.

It may be here stated that, although there are principles and clearly-defined rules laid down for our guidance by the great masters in obstetric surgery, yet we find them but approximately correct when we come to put them to the test of practice; for we have the scheme of relation of operations to the different degrees of pelvic contractions so carefully reduced to figures that one is tempted to think he has nothing to do but to invariably follow the rule. So, when he has discovered in his patient the first degree of contraction, he has but to introduce the forceps and deliver; or, when he has discovered the second degree of contraction, introduce the hand and turn; or, when in the third degree, perforate; or, in the fourth, perform "Cæsarean section." I need not say here that we cannot pursue this practice either rigidly or uniformly, for by so doing we would be often woefully disappointed. I have no doubt gentlemen present have had charge of a case of labour where the pelvis, although contracted, was not so beyond the first degree of contraction, and yet they have failed in the use of the forceps, even when perhaps they have exerted a greater power than prudence would sometimes dictate. The perforator is the instrument which is usually taken up after having experienced failure with the forceps; but, as this and all instruments associated with it in cases of craniotomy are necessarily not only destructive of the life of the child, but are found, even with the greatest care, to inflict occasionally serious injuries upon the soft parts of the mother, so that one is often inclined to ask himself the question—Is there no alternative? And, without hesitation, I am bound to answer the question in the affirmative; for as the forceps are found, as stated, to be unsuccessful in some of these cases, should we not, before contemplating the destruction of the child, take into consideration—if possible, perform—the operation of podalic version, and by so doing give the child another chance for its life? It is not for a moment to be supposed that I am presuming to advance any new theory, for version under these circumstances was practised by some of the ancients, and latterly it has been revived, the subject elaborately worked out, and the operation confidently recommended, by the late Sir J. Y. Simpson. Since his day, the same has been embodied in the works and teachings of some of our highest authorities.

I know, however, that it is a practice so very rarely adopted either here or elsewhere, and I believe it is of such value and importance, that I am justified in craving for it the careful consideration of the members of the Society.

I have, in not a few cases, successfully performed the operation of turning, after the natural powers of the mother and the forceps had failed, and when, under the usual line of action, no other resource was left but the destruction of the child. I most candidly confess I was very slow and loath in believing, with Sir J. Y. Simpson, that the head could be brought through a narrower pelvis when its base offered at the brim than when the vertex presented. I am now, however, from my own experience, satisfied that an attempt should be made in many cases to deliver by turning, when the child is known to be alive and when other means have failed.

It should, perhaps, be stated here that I believe it is not altogether so much because the base of the child's skull will pass through a pelvis which is found to refuse the admission of the vertex as that we find the narrowing of the pelvis often confined to one side; and if, in turning in such a deformity, we can manage to get the bi-parietal diameter towards that side where there is the largest space, and the bi-temporal into the narrowest space, then the extraction, I have found, becomes greatly facilitated.

The following cases, which have come within my own practice, may be offered here in illustration of the subject under consideration:—

Case I.—Mrs. _ had been in labour for some time, and in the hands of a midwife, when Dr. N. was sent for, who, after a long and cautious trial of the long forceps, found it impossible to advance the head, and was obliged to desist. He asked for my assistance, and after I had made myself acquainted with the character of the case, and although I discovered the difficulty to arise from the promontory of the sacrum projecting forwards and downwards on the right side, so as to diminish at this point of the brim the conjugate diameter to some extent, I was induced, because of more than ordinary anxiety exhibited to have a live-born child, to make another trial of the forceps, but I also failed. After making ourselves sure that the child was alive, we administered chloroform before attempting to turn. I introduced the left hand into the vagina, and with the right hand applied externally, the knees and feet were got towards the os. I seized hold of the latter, brought them down, and when the limbs and buttocks were extracted, we were encouraged to find that the child still showed symptoms of life. After placing the cord in the safest position, and after giving and taking a moment's rest, I proceeded to complete delivery by bringing down one arm, and then the other. When the arms were brought down, very considerable exertion was necessary in the direction of the axis of the brim before the head could

be got away.

I believe about four minutes elapsed from the commencement of the operation of turning till the complete extraction of the infant. It was not long till it breathed, and full respiration established. The infant, a male, was strong, and considerably above the ordinary size. In consequence of being placed under the complete influence of chloroform, the mother was quite unconscious of pain or suffering during the whole process of this otherwise severe operation, and which contributed so largely not only to her ease, but to the safety of her infant. Dr. N. has since told me that she made a good and a rapid recovery, and left her bed, as women of the poorer class in life usually do, in a very few days.

Case II.—Mrs. M'C. had been ill some hours when I saw her at the request of Dr. M. The os was fully dilated, and the pains were strong, but the head showed no disposition to enter the brim. I made an examination of the parts, and found a knuckle on the left side of the promontory of the sacrum.

The long forceps had been applied, and failed. I again made another attempt with them, but did not succeed. I was obliged to withdraw them, as I saw no chance of bringing the head down. Our patient was then placed under the influence of chloroform, the hand introduced, the child turned and brought away alive; respiration was established, as manifested by a strong and vigorous cry. The mother made a good and uninterrupted recovery, dressed and walked into the next room on the tenth day. Without dilating farther, I may just say that the difficulty in this case was increased by the size of the child, which, when weighed, proved to be 14 lbs. 2 ozs.

Case III.—Mrs. M'K., ill in labour for the fourth time. She was delivered of her first child with the forceps; of her second and third by craniotomy. I found her very ill; the os dilated, but making no further progress. Fortunately the liquor amnii was not all away, and I decided at once upon turning. This woman refused to take chloroform, but had great command of herself. I therefore entered upon the operation by introducing the right hand, as I believed the child presented with the posterior-dorsal aspect.

I found the pelvis not very roomy, and the brim somewhat narrowed on the left side of the sacrum. However, I passed the hand with some difficulty up to the limbs, hooked a knee with my finger and brought it down, and extracted the child with more ease than I expected. The child breathed, but died in a very few minutes. The mother made a good recovery. I shall not occupy the time of the Society with the details of other two cases, however interesting—suffice it to say that the pelvis was in each under the normal size. The forceps were tried, but failed, and afterwards turning was successfully accomplished.

Before concluding I should not withhold the fact that I have turned in several cases where I had afterwards to

reduce the size of the head before I was able to get it away. Still I think I have stated enough to satisfy the sceptic that a man is justified in attempting to deliver by turning, where the child was discovered to be alive, when other means had failed.

Dr. Lindsay felt he could not criticise Dr. Dill's paper. He had been an old pupil of his, and he had listened with as much benefit that night as ever he did under his teaching. He was pleased with the statement that a woman should never die undelivered. He wished to state the facts of a case which occurred in his own practice, and then to ask the opinion of the Society, and also that of Professor Dill. The case was that of a patient rapidly sinking from pneumonia. There was no chance of saving the child or prolonging life, and was he right in delivering?

Dr. Beck thought, as far as Dr. Lindsay's question was concerned, he would deliver at once, but if he was certain no good could come of it, he would leave matters alone.

As to Dr. Dill's practice, as laid down in his paper, no second opinion should be offered; the only point was the difficulty of turning. He mentioned some illustrative cases. His difficulty was in the head slipping when very high up, but he always easily delivered by version. All the children lived but one.

Dr. Dempsey's experience was altogether in favour of turning. He thought it was a shocking thing to perforate the head. He met a case in practice where craniotomy had been performed, and the child taken away piecemeal. Afterwards pregnancy supervened, and he delivered a large living child with the forceps.

Dr. Wales, in thanking Dr. Dill for his paper, referred to the experience of a large number of men in support of turning. He believed in the line of action as laid down in the paper, but thought that the difficulties of turning were rather under-estimated, and that it was not an operation to be recklessly undertaken by every young practitioner. Contrasted with the forceps operation, he believed it more difficult, especially for the inexperienced.

Dr. Dill, in reference to Dr. Lindsay's question, said that although he believed it right that a woman should never die undelivered, still, if in a case he had not the shadow of a hope for the child, he would not interfere, because the operation of delivering under such circumstances always caused more or less shock. If it prolonged the mother's life one hour, he would deliver. On the other hand, if she were dying, and must die, and no chance of relief, he would not operate. He said that the remaining portion of the subject, as indicated in the introduction to his paper, would be brought before the Society's next meeting.

George F. Wales

Tenth Meeting of the Society was held on Tuesday March 26th 1878.

Present, Dr. Wales (President), Drs. Murney, Moore, Fagan, Workman, Esler, Browne, Whitla.

Dr. Whitla read a letter from Rev. William Johnston thanking the Society for their kind letter of condolence.

Dr. Murney exhibited a lower extremity removed through upper third of femur for compound comminuted fracture.

Dr. Fagan exhibited a large urethral calculus removed from a patient. Also a knee joint for which he performed the operation of amputation through the thigh.

Paper:¹ Dr. Fagan showed an interesting specimen of “calculous disease” of the urinary organs. The genito-urinary organs were removed entire. The kidneys were enormously enlarged—the right weighed 31 ounces, and the left 14; the capsule was adherent; they were lobulated; the pelvis dilated. The ureters were of the calibre of the small intestine. At the point of entrance of the left into the bladder was lodged a calculus the size of a walnut. On the opposite side was another of similar dimensions, but not in the ureter. Through the base of the bladder, behind the prostate, a sacculus, the size of a small orange, protruded; in this were lodged two calculi. There was another calculus in the prostate. The penis was very large, and the wound into the urethra remained unclosed, through which Dr. Fagan removed a calculus that was situated a couple of inches anterior to the bulbous portion. The history of the case was narrated by Dr. Fagan as follows:—

George Stockford, aged thirty-five, was admitted under my care at the Royal Hospital, on the 16th of March, 1878. He presented a wasted, anxious appearance, showing unmistakable signs of long-continued suffering. He stated he suffered from kidney disease. When I examined him, I found he had incontinence of urine, and a calculus impacted in the urethra about an inch and a half anterior to the bulb. Ten years previous to the date of admission he suffered from severe aching pains in back and over the regions of both kidneys, after which he noticed his urine become darker and tinged with blood. This condition continued for about a year, when he was admitted to the hospital, under Doctor Cuming, for disease of the kidney, and after some time was discharged, improved in every respect.

In about two and a half years after leaving hospital, he again began to experience pain over the kidney and in the region of the bladder. Blood appeared again in the urine, and he suffered from dysuria. Matters continued thus till about two years ago, when he passed two small stones per urethram. He now felt for the first time the presence of a small body in the urethra, which slowly increased in size. He gradually lost control over

the bladder, and was compelled to wear a urinal. The pain produced by the calculus was sometimes of an excruciating character. Before passing the calculi, he suffered frequent attacks of nephritic colic.

Two days after admission I incised the urethra over the site of the calculus; the tissues were very much thickened, and I had some slight difficulty in turning it out. Its long diameter was over an inch, and was placed transversely in the urethra. From before backwards it measured eleven lines, and in thickness five lines. It weighed something over a drachm. It was composed of an uric acid nucleus, coated with copious deposits of phosphates. It was channelled in its upper and lower surfaces by the urine trickling past it.

A few days after the operation he complained of great pain over the region of the right kidney. He suffered from constant vomiting, and died ten days after from exhaustion.

Dr. Browne, who had seen the patient from whom Dr. Fagan's specimen was taken, thought that, though the operation had hastened his death, nevertheless he was right in operating. He detailed a case of his own, where he was consulted by a patient for stricture, though he could only get in a No. 3; urinary fever, with high temperature and rigors, supervened; pulse very high, and pain set in over the right kidney, and death ensued. He found, on making a post-mortem examination, that the capsule of the kidney was very much enlarged, and filled with pus, and that a large calculus was lodged in the bladder, which had caused ulceration and the escape of urine into the peritoneal cavity. Had he got in a lithotrite in time he could have prolonged if not saved his life.

Dr. O'Malley thought the specimen a very rare one, and he believed that Dr. Fagan was right in operating.

Dr. Wales, in thanking Dr. Fagan for the specimen, commented upon the evidences of diseased action, showing how dependent the different parts of the genito-urinary tract were upon the proper and healthy state of the remainder. He thought that the specimen should be brought before the Society again after the kidneys were opened and the calculi examined.

Paper:¹ Mr. Fagan showed a specimen of diseased knee-joint which he removed a few days before by amputation at the lower growth of the femur.

The end of the femur was enormously enlarged, and in the inner condyle a large cavity, containing a sequestrum, existed; this also contained a quantity of pus, and communicated with the joint; the rest of the cancellated portion was expanded, soft, and friable, and infiltrated with degenerated inflammatory products. The head of the tibia was in a somewhat similar condition, and contained a small circumscribed abscess. The articular cartilages and semilunar fibro-cartilages

¹ [Dublin Journal of Medical Science, 1878, v66, p331.]

¹ [Dublin Journal of Medical Science, 1878, v66, p260.]

were nearly all destroyed, and there were attempts at bony ankylosis here and there. Synovial membrane partly destroyed; what remained thickened and pulpy; tissues around joint infiltrated with fatty and gelatinous matter.

The specimen of diseased knee-joint I have just now shown you, I removed by the mixed method of amputation at the junction of middle and lower thirds of thigh, on the 13th of the present month. The history I consider both interesting and instructive. I saw the lad at my own house, just two years ago, at a comparatively early stage of the disease, and the following are the notes I had then taken of the case:—

F. P., aged nine years, was brought to my house on the 14th April, 1876, suffering from an affection of the knee-joint. He had the appearance of an average healthy lad. The limb was encased in a gutta-percha splint, the foot supported by a band passed round the neck, and he was able to get about pretty nimbly on crutches. There was no contraction, nor did he suffer any pain on pressure, although I used a considerable amount; however, the joint, as a whole, was very much enlarged. The condyles of the femur expanded, and there was a good deal of effusion into the joint and the pouch under the quadriceps muscle. The history I got from the mother was that she looked on him as a particularly healthy child up to last September (seven months before I saw him), when he began to complain of pain in the knee, which prevented him sleeping. As there was no alteration in the shape of the knee and no history of traumatism, it was looked on as rheumatic.

In November it began to swell. He was seen by a medical man, who recommended the joint to be strapped and a splint applied. Under this treatment it improved somewhat, when he began again to run about. After a little his condition got worse, when he was confined to his bed, and a starch bandage applied; after some time this was removed, and the joint painted over with iodine. The health began to give way about this time, and the joint had increased to the size it presented when I first saw him.

About February he was seen by another medical man, who put the limb up in the gutta-percha splint, and recommended him to take plenty of open air exercise on crutches. Under this treatment his general health began to improve, and he presented the appearance already described when I first saw him.

As it was solely with the view of getting my opinion on the case that the mother brought the boy to me, I gave it to her very unreservedly. (I may mention here that the opinion I formed as to the condition of the joint was that the disease began in some of the inter-articular tissues, probably from a strain of the crucial ligament; that it had expended itself most on these tissues, which became very much swollen and infiltrated; that the bones had become secondarily involved, but not to any great degree; and that there was a good deal of

inflammatory infiltration into the tissues around the joint.)

My opinion, as given to the mother, was—that although I did not look on the joint as hopelessly diseased, my experience led me to think that unless it speedily showed symptoms of improvement it would soon become so; that there were some encouraging features about the case, such as absence of pain when pressure was made over the ends of bones, his ability to take exercise while the joint was kept at complete rest; that the principles of treatment as laid down by her last medical attendant should be carefully adhered to; that if after this line of treatment had been carried out for some time, and was followed by no improvement, and especially if there was a retrograde tendency, I would unhesitatingly recommend excision of the joint before the disease had extended so far that this operation could not be entertained. As she was going to some friends in Dublin at the time, I recommended her to have the opinion of some eminent surgeon there.

I heard no more of the case till about three weeks ago, when the mother called on me again to say that a local practitioner recommended her to have her son's leg amputated, as the only means of saving his life, and that she wanted my opinion.

She told me that after she last seen me (just two years ago) she took her boy to Dublin, and, on the advice of a surgeon there, continued the expectant method of treatment as already described. Matters gradually got worse, the characteristic changes both in the joint and the constitution slowly but surely taking place; and, after two years of suffering, when I again saw him it was a question whether amputation could be entertained. After examining the condition of the kidneys, I recommended operation, and two days afterwards I removed the limb in the manner described. Since the operation his progress towards recovery has been uninterrupted.

Dr. Murney moved that the Secretary be instructed to procure from the Clerk of the Crown a copy of the charge against, and the punishment inflicted upon, Dr. O'Hare at the Spring Assizes of 1878 (Belfast).

He also gave notice that he would move at next meeting that the said document should be forwarded to the Branch Medical Council for their consideration. The first resolution was carried unanimously (2nd by Dr. John Moore).

The time of the meeting having expired it was agreed that Dr. Dill be requested to postpone his paper till next meeting on the condition that it should be the first business transacted.

John Moore

Eleventh Meeting April 9th Tuesday

Present, Dr. Wales (President), J. W. Browne M.D. Vice-President, Dr. Dill, John Moore, Fagan, O'Malley,

Dempsey, McConnell, Esler, Speer, Workman, Whitla Honorary Secretary.

Dr. Fagan exhibited two patients, one with cervical spinal disease treated by jury-mast apparatus of Sayre's, the other with dorsal spinal disease treated by Sayre's ordinary plaster jacket.

Dr. Dill read a paper upon "Gastro-elytrotomy and ablation of the uterus as substitute for the cæsarean section".

Paper:¹ PROFESSOR DILL said: Mr. President,—Having at a former meeting of the Society submitted for consideration the subject of podalic version, and having recommended its practice when other means had failed—to-night, I beg to offer a few observations on a couple of operations which have been proposed as substitutes for the Cæsarean section. These operations are known by the names of (1) gastro-elytrotomy and (2) ablation of the uterus; and although they have not been attempted here or in these countries, yet, as they have been performed, and that successfully, in the United States of America and in Germany, I think I am justified in claiming for them at least your careful attention. I may here mention that the only mention I find in any of our text-books or English works on midwifery, is by Dr. Playfair, who, in his "Science and Practice of Midwifery," gives but a very brief account of gastro-elytrotomy, whilst extirpation of the womb is never alluded to, so that it is from foreign works and periodicals the fullest information may be obtained regarding both operations.

When we consider the great mortality which is associated with the Cæsarean section, we are only surprised at finding obstetricians not more generally and zealously pursuing inquiries towards devising other operations by which greater confidence might be entertained by the operator, and higher hopes of recovery held out to the mother.

The Cæsarean section may be still admitted to be the most serious operation which the obstetrical surgeon is called upon to perform, and even supposing the patient may recover, she is in danger of becoming again pregnant, of rupture of the old uterine cicatrix, and of escape of the ovum into the cavity of the abdomen, whilst the Cæsarean section must be resorted to again.

The first operation which was suggested and practised as a substitute for the Cæsarean section was symphysiotomy by Sigault, in the year 1763, and from which for a time great hopes were entertained. Very soon, however, this operation got into sad disrepute, and it was given up because of even a higher mortality than was found to follow the Cæsarean section.

In comparison with these two very serious operative procedures, I would beg to draw attention to two other operations (which are considered by those who

have a right to form and express an opinion on the matter) as more hopeful. These are, as already stated, "gastro-elytrotomy" and "ablation or extirpation of the uterus." Gastro-elytrotomy was performed by Jörg, Ritgen, and Buden, and it has been recently revived and practised by Dr. Thomas of New York. I may here be allowed to state the different steps in the operation, and I shall do so as briefly as possible. It is considered necessary, in the first place, or before the operation is entered upon, that the os uteri should be either dilated or dilatable.

The first step in the operation which the surgeon must make is an incision from the anterior superior spinous process of the ilium to the symphysis pubis, and through the abdominal wall until he reaches the peritoneum. The second step is, the peritoneum, in place of being incised, must be disengaged, raised and turned back with the finger or with the handle of the knife, so that a free entrance to the vagina may be made, and the os uteri easily reached. The third step is, the os and cervix uteri should now be made to point toward the wound, which may be done by drawing them into the iliac fossa by means of a blunt hook in one hand, and with the other depressing the fundus uteri, and thus, by these two apparently opposing forces, the os uteri is brought into the open wound. The fourth step in the operation is the introduction of the hand into the uterus, and the child is brought away by turning; or the forceps may be applied when the head presents, and the child extracted by this instrument.

The advantages of this operation over the Cæsarean section are at least theoretically obvious:—1st. The peritoneal cavity is not penetrated, and consequently no blood or other fluid can enter the peritoneum; 2nd. The uterus is not incised, and therefore the danger of peritonitis and metritis is much reduced; 3rd. With our present knowledge of ovariectomy and its results, no one need really say that there is anything in the operation of gastro-elytrotomy to prevent it from being favourably entertained and practised under certain circumstances, and with good hopes of success. And now, as we are to suppose our patient does recover, we must expect that she may become pregnant again, and then, as in the case of the Cæsarean operation, the same difficulties and dread dangers must be encountered a second time. And because of this, Dr. Edward Porro has proposed a measure by which a recurrence of pregnancy is absolutely prevented. He proposed to himself and resolved upon the operation of ablation of the uterus, which he performed with the satisfactory result of the recovery of the mother. So lately as in the year 1876, M. Rein published a paper with the title "Extirpation of the Gravid Uterus as a Substitute for the Cæsarean Section," the result of experiments upon some of the lower animals. M. Rein claims for this operation the following advantages:—1st. Only a very trifling or insignificant amount of hæmorrhage during or

¹ [Dublin Journal of Medical Science, 1878, v66, p422.]

after the operation; 2nd. No important organ capable of lesion is retained in the abdominal cavity; 3rd. The impossibility of a fresh or repeated pregnancy.

Professor Spraeth has reported the case of a patient who had undergone this operation, and he states that the woman made a rapid recovery.

And now, Mr. President, with your permission, I may place the whole matter before the Society by way of a query. Is either gastro-elytrotomy or ablation of the uterus to be accepted as superior to, or are they to be supposed as giving the mother any advantage over, the Cæsarean section?

For my own part, I would answer that, with our very limited knowledge I should not too hastily come to a conclusion, much less reject the proposals as not to be entertained, for experience alone can solve the difficulty; and further, I am disposed to say that obstetricians should not pronounce too severe judgment against gastro-elytrotomy and complete extirpation of the womb, as they have been already performed with some success, and as they are at present our only substitutes or counterpoise to the extreme dangers of the Cæsarean section. Moreover, these operations are yet but upon their trial, and it is to be hoped that further experience will justify the sanguine expectations held out to us by Drs. Skene and Thomas, and Professors Ritgen, Spraeth, and Baudelocque, the expression of whose opinions on any of the great questions springing either from obstetric medicine or surgery should not be lightly esteemed by us.

We are but on the threshold of this inquiry, and if any real advance is to be made it can only be by adopting a persevering attitude, and by a careful observation and study of clinical facts and operative results, without drawing from them too hasty or too positive deductions.

DR. BROWNE said from the paper he learned that the peritoneum was treated in exactly the same way as in ligature of the external iliac artery, and he understood that Dr. Dill advocated the operation on the ground that that membrane was not injured. As for himself, he always saw that the peritoneum was injured. He gave the statistics of Storer of the results of ligaturing this vessel: out of 24 cases, 16 died. His incision was through the rectus muscle, from umbilicus to pubis. As far as the removal of the uterus was concerned, he believed there was as much danger of peritonitis from the operation as in the Cæsarean section. He believed that in all such cases the spray should be used, and showed its results from the success of Spencer Wells, and others.

DR. JOHN MOORE thought he could not throw much light upon the subject, which was an obscure one, and likely to remain so. The operation of the Cæsarean section was of so rare occurrence that only one or two in a generation were called upon to perform it—a state of things preventing any one medical man having any-

thing but a very narrow and limited experience. Many years ago it was the lot of a medical man to operate in Belfast, but no case had turned up here since, except one in hospital, and for various reasons the operation was deferred until too late. To one group of the cases demanding the Cæsarean section—malignant disease of the uterus—the operation recommended by Dr. Dill was inapplicable, the difficulties then being so great that he believed no man was justified in attempting it.

DR. FAGAN felt he was anticipated in his remarks by the previous speaker. He knew little about the subject matter of Dr. Dill's paper, and felt obliged to him for bringing it before him. He thought one should be very careful, indeed, before undertaking any operations like those discussed; but when they were forced to it, the choice lay between two very serious operations, and for his part he would say he was decidedly in favour of a clean cut.

Hole and corner operations he condemned, and thought quite too much was made out of the fact that the peritoneum was not opened. He believed the more freely this was opened the better. As regarded ablation of the uterus, he thought Dr. Dill's suggestions of more value, and should be put in force when a case presented itself.

DR. DEMPSEY thought that, from what he had heard, the operation was a scientific one, and if properly performed he did not see that any vessels of importance would be injured. He thought that the opening of the abdomen and the removal of both ovaries through their respective fossæ would be decidedly more dangerous.

DR. SPEER remarked that abortion or premature labour was not mentioned as a substitute for the more serious and difficult operations proposed. He detailed the case of a woman who had craniotomy performed in a former labour. He induced labour at the end of the seventh month after she had become subsequently pregnant, and she had now a healthy boy growing up.

DR. WHITLA (Honorary Secretary) thought that as regarded the operation of ablation of the uterus as a preventive for pregnancy, there was one operative procedure decidedly less formidable—i.e., removal of both ovaries through the wall of the vagina, as practised by the American surgeons. He gave the results of the operations, and believed that where a cutting operation was demanded as a preventive of pregnancy, it should have the preference.

DR. M'CONNELL thought, from what he had heard of the matter, he would decidedly wait for further light before he made up his mind to give the preference to any substitute for the Cæsarean section.

DR. ESLER agreed with the remarks of a previous speaker, that the operation comes so seldom that it is hard for one man to have much experience. He saw many disadvantages in cutting from the middle line—danger to important vessels and nerves. As regarded the question of ablation, he would rather deal with it in

a more conservative manner, and recommended the use of injections to prevent pregnancy. He narrated a case bearing upon this point.

DR. WALES (President), in thanking Professor Dill personally and also on behalf of the Society, said he hardly felt competent to express an opinion on the nature of the operations. He had watched the mortality of ovariectomy for many years, and saw that even now it was continuing to grow less and less; but he was sorry to say that he failed to see the revolution in obstetric surgery which he had expected would follow the splendid results of Wells, Keith, and other workers. They had it before them in a way unmistakably demonstrated that the dreaded peritoneal cavity could be opened with impunity, the intestines and viscera sponged over, replaced, and uninterrupted recovery ensue; and with this fact before him, he would not think much about whether he reflected or cut the membrane. He could not realise how the operation of gastro-elytomy could be performed without a good deal of stretching of the peritoneum.

PROFESSOR DILL, in replying to the remarks, said that those who spoke on the subject of the peritoneum being injured, seemed to forget that in the Cæsarean section this membrane is twice cut through, and after this you come to the bleeding uterus. If it was a case of only going through one layer, he would hesitate before recommending any substitute; but it was different when he remembered that the layer over the uterus must be incised also.

As regards the question of removal of the ovaries per vaginam, he would have discussed the question raised by one speaker, in his paper, only he thought that the title of his paper confined him to the points about the uterus. On the whole, he said, he must feel that the patient would have a better chance under these operations than in many cases after craniotomy, when the pelvis is very narrow; and gentlemen should remember that these operations were only suggested to meet cases where it was found impossible to extract the *fœtus per vias naturales*.

In reference to Dr. Murney's motion on the paper for the evening the Secretary explained that in accordance with the resolution of last night of meeting he called upon the deputy Clerk of the Crown who advised the Society not to press him for a copy of the charge and verdict against Dr. O'Hare.

He also informed the Secretary that the secretary of the Branch Medical Council had obtained the document and would very likely take action in the matter as he presumed he intended laying it before the Branch M. Council.

This explanation was considered very satisfactory and in the absence of Dr. Murney Dr. John Moore withdrew the motion.

George F. Wales

Twelfth Meeting of the Society was held April 30th Tuesday at 8 p.m. in the Museum of the Belfast Royal Hospital.

Present, Dr. Wales (President), J. W. Browne, Fagan, Dempsey, Whitla, O'Malley, Kirker (visitor) and D. Johnston. Several students.

Dr. Whitla showed specimen of diseased lungs and cancer of liver.

Paper:¹ Dr. WHITLA gave the following notes of a case:—A. G., aged eight and a-half years, an active, healthy girl, had been in her usual health and spirits on the evening of the 4th instant at 7.15 p.m., when she was thoroughly enjoying herself at play. She suddenly complained of a pain in her right side in the mammary region, which was soon observed to interfere with her breathing, and, continuing in severity, she was put to bed, when some shivering was noticed. I was called to see her at 2 a.m., seven hours after the onset. She was suffering intense pain, respirations were very frequent, shallow, and irregular. Any effort at coughing caused great agony. Pulse frequent and weak, and difficult to count; temperature in axilla, 102.8°. Owing to the great dyspnoea it was difficult to get a thorough examination. On inspection there was seen to be diminished movement on the right side; on auscultation the sounds on this side were distinctly fainter.

The signs thus pointed to pleuritis, but I was informed that she had coughed up some little blood expectoration. This settled the diagnosis as pleuro-pneumonia of the right lung. There was no crepitus or evidence of solidification. I gave her 1 grain of opium instantly, and an expectorant, with carbonate of ammonia, &c., and 5 minims of tinct. opii camph. every hour, and applied hot sinapisms. At 10 a.m. she was worse; no material change, but respirations more laboured, lips getting blue, mucous râles over both sides of the chest. The alarming rapidity of the symptoms seemingly increasing every minute in intensity warned me that there was no time to lose. I put on eight leeches and cupped over them, extracting about 5 oz. of blood, with decided, but only very temporary, benefit. Dulness now appeared over the right base, changing with position, and the dyspnoea increased, the lips getting blue and cold, and she sank at 5, 21¾ hours from the time she had been noticed at play in health and glee.

He brought the case before them with the result of the post mortem examination, solely on account of the terribly short duration of the disease. She was conscious up to the moment of death.

On opening the chest about 6 oz. of bloody serum escaped from the right pleural cavity. The base of the lung was partially solid, as they would see. The pleural membrane was deeply injected, at patches showing small ecchymoses or miniature extravasations; it had

¹ [Dublin Journal of Medical Science, 1878, v66, p428.]

lost its polish, and a thin filmy structure could here and there be scraped off it, like a very fine elastic membrane, evidently lymphic; but no shreds of ordinary white lymph were to be seen anywhere.

The left lung, as would be seen, was also partially solidified at its apex, and both lungs were decidedly congested throughout. The heart was normal, and contained no clot.

DR. FAGAN said the question of abstraction of blood from children was a very disputed one. For his part he found that they bore it well.

DR. DEMPSEY said he had not seen much acute pneumonia in children so young. He believed in the extraction of blood to a moderate extent, and would extract it by leeches or cupping. He would give anti-mony, but would hardly give so free a dose of opium.

DR. JOHNSTON had seen much acute pneumonia in children, and they generally did well. He could hardly see from the viscera shown that the cause of the death was in the lungs.

The SECRETARY then cut the lungs exhibited, and placed portions of them in water, when it was found that portions from every part of the right lung sank, and also from the base of left.

DR. WALES, in thanking Dr. Whitla for the specimens, said that the case was one of great interest; it was so also from its extraordinary rapidity. The amount of the disease in the viscera exhibited was astonishing, especially as the case pointed to 21 hours' duration. His experience was altogether in favour of depletion, and was uniformly successful, especially in the first stage. Opium must be given to allay pain, and he believed it might be pushed till pain was subdued. The opium in this case had clearly no effect, though the dose was fair, but the disease was very extensive. If he had a similar case he would adopt the same treatment as had been used in this, but he thought he might likely have bled a little earlier, if he got an opportunity.

Dr. J. W. Browne showed 3 patients upon whom he operated for contracted knee joint successfully.

Paper:¹ Dr. J. Walton Browne exhibited four patients upon whom he had operated for contracted knee-joint; also the photographs of three cases upon which he intended operating.

Dr. Browne said that he had been much pleased with the treatment adopted, a few years since, at Mercer's Hospital, Dublin, by the late Mr. Morgan, which was designated by that surgeon the "immediate treatment," and stated that he intended operating in all suitable cases which should present themselves by the "immediate treatment." He referred to the classification of ankylosis of joints adopted by Morgan—viz.: (1) A firm, true ankylosis; (2) A false ankylosis; (3) Contraction; and pointed out that it was in cases of false and fibrous

ankylosis that the "immediate method" was specially applicable; he also stated that in those cases of fibrous ankylosis where some degree of "spring" is present, most hopeful results could be anticipated.

He drew attention to the difficulty of diagnosis in cases of fibrous ankylosis in which the adhesions were very short—these cases possessing no perceptible degree of motion, and simulating true or bony ankylosis—and referred to Sayers method of diagnosis—i.e., by administering an anæsthetic, and using flexion and extension of the joint; waiting for twenty-four hours—at the expiration of that time, should there be some degree of swelling about the joint, the case is one of fibrous ankylosis. He had found this method of diagnosis of service in a case of ankylosis of the hip-joint.

In three of the four cases exhibited, ankylosis was of traumatic origin; and the fourth case followed an attack of acute rheumatism, the limb being kept in a flexed position for three months. In all the cases the leg was at right angles to the thigh.

In two cases the deformed limb was four inches shorter than its fellow, and in the other two cases the limbs were two inches shorter than the opposite side. In each case the patella was ankylosed to the external condyle of the femur.

In one case the internal condyle of the femur was hypertrophied, so that when the limb was operated upon and extended, the patient appeared as if suffering from genu valgum.

He said that it had been shown by Morgan that most successful and satisfactory results could be obtained in cases of the so-called "white swelling" of the knee-joint, and that the cases he purposed operating upon had suffered for many years from chronic disease of the joint. In performance of the operation, the patients were placed under the influence of chloroform, the flexors of the thigh divided subcutaneously, and the joint forcibly and suddenly extended. The small wounds produced by the tenotomy knife were closed by pieces of lint, saturated with tinct. benzoin co. The limb was then carefully bandaged to a long splint, extending from the tuberosity of the ischium to the heel, and adapted to the contour of the limb. The splint had a foot-piece attached, to which the foot was bandaged, also two cross pieces of wood to prevent the limb rotating. An ice-bag was kept constantly applied to the joint, and was not removed until all heat and tenderness of the joint had subsided; in one of the cases ice was kept applied for four weeks.

In dividing the tendons, the only point of importance was the division of the biceps tendon. In operating, the tenotome should be inserted parallel and close to the side of the tendon, and cut from the inside or popliteal aspect towards the skin. To avoid wounding the peroneal nerve, keep the tenotome close to the inner side of the biceps tendon, and, when passed deeply enough, turn its edge outwards; occasionally it is possible to separate, by your fingers, the nerve from the ten-

¹ [Dublin Journal of Medical Science, 1878, v66, p332.]

don, and roll it inwards. In the four cases the division of all the tendons was found necessary.

After division of the tendons, and when making extension, you should be very careful, as pointed out by Morgan, to place either your own hand or the hand of your assistant in the popliteal space and support the head of the tibia, lest dislocation of the tibia should occur. Two of the cases were under treatment for three months before all pain and heat of joint had subsided; the other two were discharged in six weeks, with stiff but useful limbs. Before leaving, I had boots with thick cork soles made for them, and to-night you are able to see the amount of progression they possess.

G. F. Wales

Thirteenth Meeting May 28th '78

Present, Dr. Wales (President) in the chair, Dr. James Moore, Dr. Dempsey, Dr. Core, Dr. Clarke and Dr. J. W. Browne (Secretary pro tem), McKeown, Dr. John Moore.

Dr. Core brought forward a specimen of cystic disease of the chorion. He supposed pregnancy had been accompanied by profuse bleeding at several periods. The "mole" had extruded at the end of the fourth month.

Paper:¹ Mrs. C. R., who has had six children—the latter three syphilitic—became pregnant in January, 1878, the catamenia having ceased on the 7th of that month. The ordinary early signs of pregnancy were present for two months, when, after having received a severe fright, she fell into ill health, feeling, as she said, quite different to what she had ever done before. Slight watery and sanguineous discharges took place at intervals, up till May, from which time rapid distension, accompanied by considerable hæmorrhage, went on till 20th May, when, pains having set in, I was sent for. I found her considerably blanched, and with quick small pulse. The abdomen, as to size, had the appearance of a seven months' pregnancy. On palpation, however, a doughy, boggy feeling, marked differently from that usually present, caused me to suspect a state of matters which a vaginal examination at once clearly revealed. The uterine pains being feeble, a dose of ergot was followed by the expulsion, in a very short time, of a large hydatidiform mole, part of which I submit to your inspection. No further hæmorrhage occurred, and the lady made a good recovery.

Dr. J. W. Browne brought forward a specimen of un-united fracture of the femur in the lower third in which the union was prevented by a mass of muscular tissue.

Paper:² Dr. Browne exhibited a femur which had been removed from a woman, aged sixty years. She was

admitted into the hospital under his care, suffering from compound comminuted fracture of the left leg, oblique fracture of the right femur, and injuries of the pelvis. The case progressed favourably until the sixth day, when it was deemed necessary to amputate the left leg. At the end of four weeks, when the stump had quite healed, it was found that the fracture of the femur had not united. A few days subsequently, the patient was seized with pyæmia, and died. Upon post-mortem examination it was found that there was an oblique fracture of the lower third of the femur, and some fibres of the vastus externus had become implanted between the fragments, and prevented union taking place.

Dr. Clarke presented for Dr. Fagan a specimen of malignant epulis which he had removed from the upper jaw.

Dr. McKeown related the history of a case in which a set of artificial teeth been lodged in the pharynx and which he removed by the operation of orophagotomy.

Dr. Dempsey read notes of a case of double vagina and uterus where labour was accomplished by Simpson's long forceps.

Paper:¹ DR. DEMPSEY said: Mr. President and Gentlemen,—I was called at one o'clock on the morning of the 18th October, 1877, to attend Mrs. M. in her first confinement. She had been ill from eight o'clock the previous night with sharp pains, but at long intervals. I examined her and found the os uteri to be dilated to the size of a sixpenny piece. To ascertain its dilatability I examined her again during a pain, and this time with great difficulty I discovered the os, and was surprised to find it much less dilated than when I examined before.

It immediately occurred to me that there was some abnormality, and I then found there was a bridge of tissue stretching across the vagina, dividing it into two compartments—an anterior and a posterior. This septum was about one-eighth of an inch in thickness, soft and elastic in structure, and it extended from each labium minus backwards to the uterus. It did not pass straight across the vagina, its attachment on the left side being nearer the fourchette than on the right side. The anterior canal was therefore somewhat larger than the posterior. The os and cervix uteri in each canal had all the characters of normal development.

The head was presenting, and the liquor amnii had escaped. As the labour was likely to be tedious I left her, and returned about six o'clock. The os at this time in the anterior canal was dilated to the size of a crown piece; in the posterior canal to the size of a half-crown piece. I could pass my finger through one os uteri over the septum into the other, so that the uterine cavity was not divided. The pains from this time were quick and strong, until about nine o'clock, when they came at

¹ [Dublin Journal of Medical Science, 1878, v66, p334.]

² [Dublin Journal of Medical Science, 1878, v66, p335.]

¹ [Dublin Journal of Medical Science, 1878, v66, p427.]

longer intervals. At nine o'clock the anterior os was nearly fully dilated; the posterior remained as before—about the size of a half-crown.

At each pain the head of the child was pressed strongly against the bridge of tissue between the duplex os uteri, which completely obstructed its advance.

I endeavoured to keep it aside during the pains, but they came at such long intervals and were so weak, that no advance was made. At 11 o'clock a.m. there was an escape of meconium, and I then determined to deliver at once. I put on Simpson's long forceps, and made gentle traction with one hand during the pains, and with the other tried to push the obstructing septum over the child's head.

Just when I believed I had done so effectually, and that all trouble with it was past, and made stronger traction, there was immediate evidence of laceration, which continued with every pain until I brought the head down on the perineum.

The child was apparently dead, but after some efforts it began to breathe regularly and lived.

The placenta was expelled about fifteen minutes afterwards. There was not much hæmorrhage immediately after confinement, but during the day and throughout the night there was a great deal of a trickling kind, which ceased altogether the following morning—viz., October 19th. A sharp attack of metritis now set in, with high fever and quick pulse. The pulse reached 140 in the minute on the third day after confinement. There was intense tenderness over the uterus, which felt very large, and altogether she was in an alarming state for a few days.

Under treatment of the prescribed kind she recovered, and was able to be up on the 13th day after confinement.

I have never since had an opportunity of examining her, so cannot tell the extent of the laceration, but, from the noise of the rent, I believe it must have been extensive and implicated the cervix of the uterus (at least the part between the ora uteri), as well as the septum. As malformations of this kind are rare, I thought it would be interesting to read the notes of this case to the Society. During a term of four years I find only one such case recorded in *The British Medical Journal*, and that by Dr. Murray, of Durham College, but in his case the uterus was also divided. To understand how this abnormality took place, we must look to the usual mode of development of these parts in the fœtus.

The vagina, the cervix of the uterus, and the lower part of body of the uterus are developed from the genital cord—the genital cord itself being formed by the union below of the two Mullerian ducts. From these ducts above the genital cord are developed the upper part of the uterus and the Fallopian tubes.

In this case the lower portions of the tubes of Muller did not unite into one single tube, but remained as two distinct canals, and the result was a double vagina, os,

and cervix uteri. The development of the rest of the uterus had gone on in the usual way, and there was only a single cavity. I may state Mrs. M. was not aware there was anything unusual in her development.

Dr. Core was appointed Treasurer in place of Dr. Fagan, resigned.

Dr. Browne proposed a vote of thanks to Dr. Fagan, seconded by Dr. John Moore.

Alexander Harkin, President

Annual Meeting Session 1878–79

Present, Dr. Wales in the chair, Dr. Wheeler, Core, Esler, Dempsey, Anderson, Browne, Moore, McKee, Wadsworth, Speer, Graham, McKeown, Workman, Aickin, Browne, Dill, Whitla.

The Annual Meeting was held in the Society's Rooms, Royal Hospital, on Thursday, November 7th, 1878. The Chair being taken by the President, Dr. Wales, [and the minutes of previous annual meeting having been read] the following Report was read by the Hon. Secretary:—

The Council have pleasure in submitting to the Members of the Society their Report for the Session terminated.

Thirteen Meetings were held during the Session, and the average attendance was 14.5—a number which may seem small, but which represents an improvement upon the former year, and is, moreover, the highest average attendance for several years past.

The President's suggestion of opening the Session with a debate proved a decided success, and the discussion upon Alcohol lasted for four nights.

The Council have with regret to mention the death of one of the most respected and beloved Members of the Society, Dr. Henry M. Johnston, an ex-President, whose genial manner and sound common-sense observations will long be missed at our Meetings.

The Council have also to report the loss of Dr. Spence, cut off in the prime of life by sudden disease, and also to mention their sorrow at the national loss of our most renowned and illustrious Honorary Member, Dr. W. Stokes, of Dublin,

Eight new Members joined the Society during the Session, leaving a balance in our favour after deducting those who have left town and a few who have resigned connexion with the Society.

The following papers were read during the Session:—

Drs. Cuming, John Moore, Dill, Beck, senr., MacCormac, Wheeler, Esler, Aickin, Speer, and Whitla, papers on "Alcohol"

Dr. Esler—"The Disposal of the Dead."

Dr. Dill—"Forceps versus Version."

„ "Gastro-Elytrotomy and Ablation of the Uterus as Substitutes for the Cæsarean Section."

Ulster Medical Society
Session 1877-1878
President George Frederick Wales

Dr. Browne—A paper on “Contraction of the Knee-Joint.”

Dr. M’Keown—“Œsophagotomy, with Notes of a Case.”

Dr. Dempsey—“Notes of a Case of Double Vagina.”

Professor Cuming—“Notes of a Case of Rupture of Ovary.”

The following patients were exhibited:—

Dr. Browne—Four cases of contracted knee-joint successfully treated.

Dr. Harkin—A case of psoriasis cured by chryso-phanic acid.

Dr. Whitla—A case exemplifying the action of the acid.

Dr. Fagan—A patient from whom he removed the shaft of the ulna, and two children put up in Sayre’s plaster jackets.

The following specimens were exhibited:—

Dr. Murney—A compound fracture of the knee-joint.

Dr. Fagan—A beautiful specimen of encysted renal and vesical calculi, and a malignant epulis from upper jaw.

Dr. Browne—An ununited fracture of femur.

Dr. Core—An hydatidiform mole.

Dr. Whitla—Diseased lungs, causing death in twenty-one hours; a specimen of fibrous tumour of uterus and disease of the ovaries; an upper extremity the seat of a large recurrent tumour; a liver and gall-bladder from a jaundiced patient; a specimen of fatty degeneration of the liver; also one of diffuse smooth cancer in the same organ.

Important changes have been made in the financial department of the Society. The services of the Messenger have been dispensed with, and his salary to be devoted to the increasing and overhauling of the Library,

Dr. Fagan resigned the Treasurership during the Session, and Dr. Core kindly consented to act.

A Microscopic Committee was appointed last Session, but owing to its size was found impracticable; and the Council, in order to increase the efficiency of this branch, have resolved to appoint a Microscopic or Pathological Secretary to examine all specimens referred to him by Members or by the Society.

A ballot having been taken, the following Members were elected:

Dr. Harkin: **President**

McKeown and Browne: **Vice-Presidents**

Council [votes]: Wheeler (14), Cuming (9), Fagan (8), Smith (7), Moore (7), Anderson (7).

Treasurer: Dr. Esler.

Librarians: Core and O’Neill.

Pathological Secretary: Dr. Workman

Honorary Secretary: W. Whitla.

Drs. Graham and Dempsey: **Auditors.**

Thursday November 21st was fixed as the day. Drs. Dill, Murney, Moore, Wales, Treasurer and Secretary were appointed to act as a Dinner Committee. The Imperial Hotel was arranged to be the place.

A. Harkin, President

ULSTER MEDICAL SOCIETY

SESSION 1878–79

First Meeting of the Session was held in the Royal Hospital on Tuesday 28th November 1878

Present, Dr. Wales (Ex-President), Dr. Harkin (President), Professor Dill, Dr. Aickin, O'Neill, Esler, Core, Dempsey, Whitla.

Dr. Wales after introducing the President, Dr. Harkin, in a suitable speech, vacated the chair which the President occupied.

A ballot was taken and Drs. Clarke and Riddell were elected members.

Dr. Young proposed by Dr. Whitla seconded by Dr. O'Neill was nominated as member.

Dr. McKenzie proposed by Dr. Esler seconded by Dr. Wales, Dr. Withers proposed by Dr. Esler seconded by Dr. Wales, were proposed as members.

Dr. Whitla, the Honorary Secretary, was directed to obtain a copy of the Register and Directory for 1879.

Dr. Harkin then with some preliminary remarks, read his opening address choosing his subject "The milk feeding of infants".

Paper:¹ GENTLEMEN,—In accepting, at your invitation, the honourable position of President of the Ulster Medical Society, my first duty is to thank you most warmly for the high compliment you have conferred upon me, and to express the hope that, with the aid of the Council and the indulgence of the Members of the Society, I shall be enabled to preside at its discussions to the general satisfaction.

I have great hopes that a new era has dawned on our time-honoured Society. Last session afforded evidence of renewed energy and life, and discussions on important topics and valuable monographs contributed to maintain an interest in its proceedings. I have learned, too, that in the coming session there is every prospect of progressive improvement.

I trust that the younger members will not hesitate to bring forward original papers and disquisitions on medical subjects through fear of friendly criticism, and that the seniors will endeavour to overcome the vis inertiae by which they are too liable to be influenced, and that they will cull from the repertory of their note-books some of their important cases and theoretical speculations. Labouring thus in unison, we may have good reason to hope that when the session terminates the retrospect shall be satisfactory to us all. My able and accomplished predecessor in this chair treated in an exhaustive manner, in his opening address, the subject of the great advancement of medical science—its

conquests and its triumphs in modern times. The task which I have imposed on myself will, I fear, be less flattering and agreeable; for it is my purpose to advance opinions adverse to those generally recognised, and to question the propriety of the teaching and practice on a very important subject—"the Milk-feeding of Infants at Nurse."

The proposition which I hope to establish is, that in the unreasonable and excessive dilution of cow's milk practised by mothers and nurses in the feeding of infants, sanctioned and taught by many members of our profession, serious injury is done to the nursing child, its natural development retarded, its growth stunted, and too often the seeds of disease and death implanted in its constitution.

Were every English mother actuated by a sense of her maternal obligations, did she nourish her baby during the early months of its existence with the food specially provided for it by the Author of its existence, defective alimentation could not, with justice, be classed as a potential cause of infant mortality, nor should it be in my power to animadvert on prevalent errors in artificial or hand feeding of children, the main resource of the fashionable dames of modern days. How strange, and how much to be deplored, that the Christian mothers of the 19th century should be as oblivious to duty in this respect as the matrons of Pagan Rome in the age of Tacitus, who, as a proof of the degeneracy of Rome in his days, laments that while in former times "grave matrons attended to their children as their first duty, they now," he complains, "entrust them to the care of some Grecian slave, or other inferior domestic."

But in addition to the class of unwilling mothers, there is another and a numerous one to whom Nature has not been so liberal, and who have not been provided with the maternal nourishment, and who are, therefore, precluded from performing that duty; and a third class who, although secreting freely, are debarred from nursing by the defective quality of their milk through a tuberculous or other taint in their system.

It is in vain that, according to the apostle, "the babe desires the rational milk without guile," for "every nurse and mother," in the words of Sir James Simpson, "thinks that she can improve upon God's food—pure and unadulterated milk." Some nurses from the very first week are in the habit of adding farinaceous food—such as corn-flour and arrowroot—to the posset of milk, in happy ignorance that it is not until the lapse of five or six months that the infant acquires the property of digesting starchy food, and that, in the absence of ptyalin, it passes into the stomach and bowels in an insoluble state, incapable of being assimilated—intestinal trouble being the necessary result of such feeding.

But the greater number—and it is with those that we have now to do—prefer to rear their children on that food alone which most nearly resembles the mother's milk, and therefore the milk of some inferior animal,

¹ [Dublin Journal of Medical Science, 1879, v67, p66.]

when a wet nurse is not provided, is depended upon for their nutrition. The milk of the ass, though suitable for some cases, frequently disagrees, and the milk of the goat is not always available, so that practically cow's milk is the chief reliance of the hand-fed child. Milk as it comes from the cow is a beautiful emulsion—a compound fluid in which sugar, curd, and oil, are mingled with a certain proportion of water— and admirably adapted to the digestive powers of the infant.

While the water and sugar are absorbed, the curd is separated by coagulation, and finally dissolved by the agency of the gastric juice, which is much more powerful in the young than in the adult, and thus greatly contributes to digestion. If then this bland fluid, moderately heated, were given without any of the improvements alluded to, especially the benevolent addition of water in scientific profusion, we should have fewer puny, sickly infants to prescribe for; fewer complaints of colic, of spasms; fewer entreaties for carminatives, for sedatives to still the voice of hunger in the poor starlings whose only requirement is to be found in a cup of genuine unadulterated milk.

But the doctor is consulted—he finds that the infant is not thriving, that it is peevish, languid, restless by night and day, that its evacuations are unhealthy, that it is constantly wetting its napkin, that its countenance is pale and anæmic, its forehead and scalp traversed by large blue veins, that diarrhœa is a frequent visitor, and that if a change do not soon occur, the gravedigger shall soon have his due—every fourth or fifth grave that is dug being for an infant under twelve months; but then—

"Tis not a life—

"Tis but a piece of childhood thrown away!

The doctor soon discovers that there is a great defect in the nutrition of the child, and inquires upon what it is fed. He is gravely answered—"Upon milk and water." He asks, why give water? Because, the nurse replies, cow's milk is too strong for the child, and we add equal parts of water—or, two parts of water to one of milk!! or frequently three parts to one of milk!!! And upon this watery diet you expect the infant to thrive, and you wonder that the water you are incessantly pouring in by the mouth is as constantly passing by urination, that its flesh is not firm, and that its bowels are so relaxed.

On inquiring of trained nurses for an explanation of this practice, I have been answered, "Oh, Drs. A. and B. always do so;" by one that she was taught the science of dilution, 2 parts water 1 milk, in the Rotunda Hospital. My reply was, "Perhaps so." I have no doubt its present masters give different advice. By another, that an eminent gynecologist in Edinburgh told her always to give equal parts. "If so," I answered, "while I have every respect for that gentleman's scientific acquirements, it is evident he has yet some knowledge to gain." But passing from the statements of monthly nurses and mothers, what do our text-books, what do our teachers

say on the subject? I shall quote from but a few, as I am sure the generality of the practice of dilution will not be questioned. Underwood, a great authority in his day, directs a portion of water to be added, leaving the quantity to the discretion of the nurse. Dr. Combe, "On the Management of Children" (p. 234, Chap. XI., on Artificial Nursing), says—"At first two-thirds of pure fresh water should be added to one-third of milk, but goats' or asses' milk does not require more than an equal part of water; after a week or two the quantity of water may be reduced to one-half, and afterwards to one-third, at which proportion it should remain for four or five months."

Some textbooks tell us to give the milk diluted with a proper amount—some two-thirds water to one-third of milk, some with equal parts. The Edinburgh Medical Journal, quoted in Brit. Medical Journal, July 15, 1873, publishes the following, among other rules, for the management of infants, prepared by the medical officers of the New Dispensary, and circulated among the visitors to the charity—further assuring us that they are very similar to those which have been issued for some years at the Middlesex Hospital and the Hospital for Sick Children, London.

After some very useful paragraphs—Paragraph 3, how to bring up by hand:—"If the child must be brought up by hand, it should be fed with milk and water out of a bottle. At first there should be nearly as much water as milk, but when the child is a month old two parts of milk should be mixed with one of water; after this the proportion of milk should gradually be still further increased, till at five or six months it is given plain." The editor of The Edinburgh Medical Journal adds this sensible remark:—"To mix water with milk is needless—too much of that is added before the poor mother gets it, and, even were it not so, the child has need of all the nourishment it can get."

This expression of opinion by the editor formulates in a few terse words my long-cherished idea, the result of my personal observation and experience during the greater part of my professional life, and to enforce its adoption and to induce my professional brethren to reconsider their teaching and practice on this important subject is the aim and object of this paper. I shall trouble you with but one other quotation from a very learned and the latest writer on the Science and Practice of Midwifery, Dr. Playfair. He says, at p. 276, Vol. II.:—"A common mistake is over-dilution, and it is far from rare for nurses to administer one-third cow's milk to two-thirds of water—the necessary dilution will be best obtained by adding to pure, fresh, cow's milk one-third hot water, so as to warm the mixture to about 96°. After the first two or three months the amount of water may be lessened, and pure milk, warmed and sweetened, given instead."

You perceive, gentlemen, dilution is the prevalent idea, with one bright exception, in the hand-rearing of chil-

dren—it is by this potent means that we shall succeed in putting a bone into children when they are young. But you will not fully realise the grandeur of this idea, the complete development of this gospel of nutrition, unless you take the trouble of following the process step by step.

In the first place, according to Letheby, the normal amount of water in good honest milk ranges from 84 to 95 per cent.—a fine foundation for the exercise of the noble act of dilution; to this the dairyman is permitted, by custom, sanctioned by the Society of Public Analysts, to superadd 5 per cent, from the cow with the iron tail; the dealer next appears upon the scene, and he is permitted by the authorities of Somerset House to add 15 per cent, on his own account, as they have declared that milk with 20 per cent. of added water should be passed as genuine.

The purchasers are thus entirely at the mercy of the dealers, who, too often, by dilution and skimming of the milk, rob it of 25 per cent. of its cream and other nutritive qualities.

According to Dr. Cameron, however, while 25 was a usual rate of dilution in Dublin, it frequently rose to 60 per cent. of added water. Let us now follow this sophisticated fluid, this ill-used aliment, to the nursery, and here we shall find that it receives the worst of all bad treatment, for before the passive infant is permitted to take the pellucid fluid it is again doctored by the addition of, not 5 or 10, but of 100, 200, or very frequently, 800 per cent. of water, by the advice or tacit sanction of the physician, and on the plea that the pearly liquid is too strong for the digestive organs of a healthy child! Surely the homœopathic nostrum of the third dilution could not compare in absurdity to this.

To what purpose, may I ask, the interference of the Legislature rendering it a penal offence in a dealer to dilute or adulterate the milk beyond a certain proportion—to what advantage the action of the magistracy who daily, in our courts of law, impose heavy penalties on conviction of the adulteration of milk, assigning as a reason that it deprives the citizens of good and proper nourishment, if heads of families, through ignorance or unsound advice, so often nullify the intentions of Parliament, and mix and destroy the most salubrious of infantile foods?

But where, I ask, in this deluge of water is the poor infant to find the necessary amount of nitrogenous and carbonaceous material? where the saline principles indispensable to the growth and development of the solid textures of the animal frame? But as those matters, so essential to vitality, are not presented to the infant, as a natural consequence defective alimentation leads to individual degeneracy, and ultimately to progressive degeneracy of the race, to wasting disease, and to death.

How sad to mark how soon the flower of human life

Hastes to its fading from its very birth!

Another newly-born ! How near ere they—

The one that's dead, the one that's born to-day!

As a general principle, it cannot be questioned that disease and premature decay are intimately associated with the nature of the food-supply. According to Ancell, milk, poor or defective in its staminal principles, will, no doubt, produce in the nursling all the effects of deficiency of food, and that debility which operates as a predisposing cause of tuberculous and other diseases (vide Ancell, "On Consumption," p. 458); and Donné informs us that he ascertained, "by direct experiment, that an inappropriate nourishment of young animals has a great effect in altering the shape and nature of the corpuscles of the blood" (vide *Microscopical Journal*, 1842, p. 245). It is a long time since Mr. Phillips declared that dilution cannot make cows' milk resemble that of women. Physiology and pathology alike protest against the false principle which I have been arraigning to-day; but my chief reliance shall be upon chemical research to upset the assumption upon which this hypothesis rests—viz., that the milk of the cow is so much stronger than human milk that it requires an amount of water, varying from 25 to 800 per cent., according to the whim of the blender, to assimilate the fluids, and adapt cows' milk to the digestive capacity of a healthy child.

In accordance with ordinary modes of reasoning, if 300, 200, or even 25 per cent. of water were required to reduce a certain liquid to the strength of another, it should only be so because that liquid was composed of elements three times, twice, or one-fourth stronger than the other. Now, is such the case with the two liquids we are comparing? Plainly, is the milk of the cow three times, twice, or even one-fourth stronger in nutritive elements than human milk? Let chemical analysis determine. In the first place, the specific gravity is almost identical, varying in both, according to conditions of health, from 1013 to 1832 (Vernois and Becquerel). According to analysis of Regnault, given in "Neligan," in 100 parts of human and cows' milk there are found—

	Cows' Milk	Human Milk
Water	87.4	88.6
Oil and butter	4.0	2.6
Lactin and soluble salts	5.0	4.9
Casein, albumen, and fixed salts	3.6	3.9
Total solids, cows'	12.6	
" human		11.4
Difference 1.2 (about one-tenth)		

Thus, on the computation that the milk is obtained direct from the cow, about one-tenth is the exact amount of solid nutriment contained in that secretion as contrasted with the milk of the mother; and upon this slender superstructure the edifice of dilution is established!

But to act in every case upon the principle of dilution is simply to become the slave of routine; and, in my somewhat extended experience, I have very seldom found it necessary to add any water to the milk provided for healthy infants, for the mere purpose of dilution. I have occasionally advised the addition of an ounce or two of lime-water to a pint of milk, not as a diluent, but as a corrective of lactic acid, which is frequently found in milk when not absolutely fresh—the normal reaction of good milk being alkaline; and often that corrective is not necessary, for if the milk occasionally disagrees on account of the varying condition of the digestive organs of the child, or from other causes, it is only necessary to boil the milk and carefully skim it before use.

Children nourished with the fresh milk of the cow present a rosy, robust, happy, and contented appearance, in marked contrast with the poor starvings fed upon homœopathic doses of milk administered in floods of water, or mingled with starchy or farinaceous diet. No one can adequately tell the amount of infantile mortality due to inefficient feeding; thousands whose deaths are annually registered as caused by teething, diarrhœa, water in the head, tabes mesenteries, convulsions, thrush, &c., and who perish in the first year of their existence, in reality owe their deaths either directly or remotely to improper feeding. Should not our sympathies, then, be directed

Towards the young souls new clothed in helpless
clay,

Fragile beginners of a mighty end?

And if we could better instruct their mothers in this all-important duty, many lives would be saved to the State, infants would not die as if to make way for others to be born, and some reparation would be made by the present race of medical men for the false teachings of other days, the traditions of which still linger and are painfully evident in many customs of modern life. When a fond mother exposes her child to a cold chilling wind, with the avowed object of hardening its constitution, she is but obeying the dictum of Dr. Underwood, who taught the mothers of the preceding generation to do so, and who testified to “the absolute necessity of inuring very young infants to endure the cold as essential to their health and that of Dr. Armstrong, another great authority, who taught at the same time that infants should be daily plunged into cold water, even the day after their birth, for the purpose of bracing up their nerves, &c. We are also confronted daily with the senseless dogma, believed in by most mothers, that because a child is teething it would be dangerous to stop a diarrhœa, and many an infantile life I have known to be sacrificed to such a vulgar error.

My great object in bringing this subject before the profession is not, I trust, a too ambitious one, if I express the hope that the medical men of the present day—the legitimate advisers of mothers and nurs-

es—will set their faces against this monstrous and wide prevailing abuse; and that, while it may be necessary in some cases for a time or in certain conditions of an infant's health to permit or advise the addition of some diluent to its ordinary pabulum, they will not permit the use of their high authority as sanctioning a process of promiscuous dilution.

(Dr. Wales thanked the President and was about to reply to the subject of the paper when Dr. Wales [sic] proposed that the meeting be adjourned and Dr. Dill seconded this.)

A vote of thanks was proposed by Dr. Wales and seconded by Professor Dill to the President for his able and interesting address. Proposed by Dr. Wales seconded by Dr. Dill that the remarks of the President's paper be postponed till that night week.

A long conversation took place regarding the publishing of the President's address and it was agreed that the President be requested to furnish the manuscript for publication in the Dublin Medical Journal.

**Second Meeting Alexander Harkin president
The adjourned first meeting was held in the
Museum upon Thursday December 5th.**

President Dr. Harkin in the chair, Dr. Wales, Professor Dill, McConnell, Esler, Core, J. W. Browne, Lindsay, Workman, Dempsey, Riddell, Whitla.

Drs. Young, Mackenzie and Withers were elected members of the Society.

Dr. J. W. Browne proposed and Dr. Esler seconded the nomination Dr. John Rea.

Dr. Wales opened the discussion upon the milk feeding of infants, and was followed [by] Professor Dill, Dempsey, McConnell, Riddell, Core, Lindsay, Esler, Workman and J. W. Browne.

Paper:¹ DR. WALES (ex-President) said: In opening the consideration of cow's milk feeding for infants, I will not go outside of the immediate question. With you we will, I am sure, mostly concur that milk as ordinary sold requires no dilution; but doubtless there will be differences in our experiences with regard to pure undiluted milk. Speaking for myself, I have frequently found it necessary to dilute milk both with water and lime-water to diminish the tendency to the formation of an indigestible coagulum even in children seven months of age. I certainly would not venture on ordering undiluted milk for a new born infant with my present ideas and experience. The irritation formed by milk coagulum must be familiar to most of us, and the difficulty of combating its consequences must be felt by all of us, as one of the trials of practice. Knowing that the casein of human milk forms light flocculi, while that of cow's milk coagulates in the infant's stomach into hard gelatinous pieces, often utterly indigestible, occasioning

¹ [Dublin Journal of Medical Science, 1879, v67, p252.]

cholera infantum, I cannot think it wrong to reduce the proportion of casein and salts in the latter to at least the proportion existing in the former by the addition of water, and lime-water also if disposed to acidity. But the difficulty as to milk-feeding is, I think, satisfactorily solved by the introduction of Swiss condensed milk (1-9) which I regard as next to a good breast, and superior to the milk of one cow. I think when its value is generally appreciated it will reduce the mortality amongst bottle-fed infants immensely.

PROFESSOR DILL said that the President, in his opening address, had acknowledged the fact that cow's milk is stronger than that of the human female; and he would therefore dilute it with a little water, at the same time adding a small quantity of sugar, in which it is deficient. He was disposed to say that where the mother fails in nursing her own child we should fall back upon a wet nurse. In cases where bottle-feeding is adopted there is more than quality to be considered—there is quantity. Some members of the profession had taken in hand to weigh a child before and after taking the breast milk, and found that from three to four ounces were taken at a time, amounting in all to about two pounds a day. Another important matter to be attended to is the temperature of the milk; it should have a mean temperature of 95° Fahrenheit. He considered this point quite as important as either quantity or quality, and thought that much injury arose from want of attention to it. He thought that if we could get over our prejudices, ass's milk would probably be the best as it comes nearer the mother's, but as society is constituted, we need not go beyond the cow's milk; but with all the care and attention which can be bestowed, it is a poor substitute for the soothing influence of a mother's lap and a mother's bosom; and no man of any experience could recommend bottle-feeding as compared with the breast. In consulting physiological chemists we find that the mother's milk varies much from first to last, becoming stronger as the child grows older, and is adapted to the child's strength up to that period when the child should be weaned. We should take a leaf from nature's book, and diminish dilution as the child advances. He would not dilute with barley-water, as some advocated, but use simply pure water. The cow's milk requires also a little alkali—depending on the state of the bowels—if loose, chalk or lime-water; if constipated, a little magnesia, and he considers Murray's solution of magnesia the best form.

DR. DEMPSEY said: Mr. President,—For the reasons which Dr. Wales has stated, with reference to the differences between the curd of woman's milk and cow's milk, I believe with him that cow's milk should be given diluted to infants in the early months of life; and it is for this reason that cow's milk is mixed with water when given to infants, and not merely because it is richer in solid constituents than woman's milk. I am in the habit of recommending the milk to be given diluted

with one-third of water, and with the addition of a little sugar. Pavy recommends sugar of milk instead of ordinary sugar. He gives one ounce sugar of milk to three-quarters of a pint of milk, diluted with water in the proportion I have mentioned. I believe many of the cases of dyspepsia and marasmus seen in infants brought up by bottle-feeding to be due more to the carelessness of those who attend them than to the fact of diluting the milk. It is the usual practice of nurses to prepare a bottleful of milk for an infant's meal. Of course, one-half of this is not taken, and what is left is either kept warm or re-heated for the next meal, or probably mixed with fresh milk and re-heated a few times more. This system of re-heating sours and curdles the milk by converting the lactine into lactic acid. Sour milk is neither nutritious nor will it remain on the infant's stomach. Another cause of sickness and wasting in infants is the too early administration of farinaceous foods. Mothers believe that because older children thrive well on them, that, consequently, they cannot be given too soon in life; but young infants, having no salivary secretion, cannot digest starchy food. If any food other than milk food is suitable for early infancy—the only one I can see to be chemically so is on prepared by Liebig. It is made by mixing wheaten flour, barley flour, a few grains bicarbonate of potash, water, and cow's milk, in stated proportions. This is made first by warming it and then boiling. The ferment in the malt, under warmth, converts the starch of both flours into dextrine and grape sugar, the latter of which gives the food a sweet taste. The bicarbonate of potash neutralises the acid reaction of the two kinds of flour and raises the alkalinity of the food to that of woman's milk. This food closely approaches woman's milk in chemical composition. With reference to the condensed milk which Dr. Wales recommends, it is quoted by Pavy that though a child fed on it appears to thrive well, and becomes plump and fat, this appearance is delusive, because under any exhausting disease, such as diarrhœa, it rapidly sinks. I think with care on the part of the nurses in having the bottles thoroughly clean and fresh, and in giving the milk in proper quantities, and at proper times, the mortality of bottle-fed children would be materially reduced. M. Guillot, the authority Dr. Dill referred to, from experiments conducted at the Foundling Hospital, Paris, calculated that a child under one month draws from the mother's breast from two to five ounces of milk at a time, and that two and a quarter pounds of milk is the smallest quantity that will suffice for the nourishment of a healthy child under one month old. I agree with the President that if the milk first taken from the cow be used, it may be given pure, but it contains very little cream, and is not so nutritious—the fatty matter rising in the gland of the cow, as it does out of it—the last of the milking being therefore the richest. For many reasons, when from some unavoidable cause the mother's milk is not available or

suitable, personally, I would prefer, from my experience, hand-feeding, if carried out judiciously and carefully, to wet-nursing. There are so many influences at work—social as well as physiological—when a wet nurse is taken into a family, tending to derange the quality of her milk, and over which there can be little control, that I believe careful hand-feeding, judiciously attended to, is a more satisfactory and preferable way of rearing children.

DR. J. WALTON BROWNE had seen very satisfactory results on bottle-feeding with cow's milk—one-third water and a little sugar of milk added, up to nine months of age. He knew where barley-water was used, mixed with the milk, with the best results. With regard to the temperature of the milk, an American writer advocated giving the milk quite cold, which prevented dyspepsia.

DR. RIDDELL agreed with the President, and would go in for milk, pure and simple. Having practised in a country for three years, where for nine months out of the twelve cow's milk could not be procured, he had seen children fed on Swiss milk, and found that the mortality was much greater than on cow's milk. He considered that the less sugar was added to the milk the better. The cow-keeper was in the habit of giving salines to increase the quantity of milk a cow would give, and this rendered it dilute. One corrective to colicky pains is to provide the child with some additional fat which is destroyed in heating the body. Half a teaspoonful of cod-liver oil, night and morning, makes a child thrive well. His own practice is to give milk in its purity, without warming. He considered wet nurses an abomination, and he very much preferred the bottle. He believed there would be fewer cases of rickets, and fewer little graves, if we confined ourselves to milk as it comes from the cow.

DR. M'CONNELL did not consider bottle-feeding and hand-feeding were at all synonymous. His experience at the union workhouse is that the bottles do not answer, as the nurses left the empty bottles and sour tubes for the child to suck, and he has therefore done away with bottles altogether. The plan he now adopts is to give an orphan child to one nurse's exclusive care, and he has increased the allowance of milk from a pint to a pint and a half, with one ounce flour and eight ounces bread, daily. There should be no fixed rule with regard to quantity, and he deals with each case on its merits, if it is at all peculiar; and with regard to quality there can be no rule, as the milk varies so much at different times and seasons. After the child is six months old he adds no water. The improvement in this system of spoon-feeding, without the use of bottles, has been very marked in the improvement of the children. He had observed that at the time of year when cows were getting large quantities of malt-grains the milk was rendered quite unfit for use, and that the same thing occurred where cows were fed on land which had been

flooded—the milk turned quickly acid and stringy.

DR. CORE remarked that the question for the consideration of the meeting was not whether cow's milk was sufficiently diluted already before it reached the consumer, and therefore should not be further diluted, but whether pure cow's milk required any dilution to make it a suitable aliment for an infant from birth. He quite agreed with a remark made by Dr. Riddell, that a great evil arose from attempts to improve the work of the Creator; but as cow's milk was not the sustenance intended for an infant, he failed to see why the acceptance of that principle should prevent us, when the natural food was not available, making such changes in the cow's milk as would make it approach more nearly in character to the human milk. The fact that not only is the casein in cow's in a larger quantity than in human milk, but that the coagula formed by the former are large, hard, and indigestible, compared with those of the latter, seems to point unmistakably to the necessity for dilution. The amount of this must vary not only with the quality of the milk, but with the age of the infant—the changes known to take place in mother's milk pointing out in this latter respect a line of practice which could not possibly be followed if pure milk were given from the first.

He thought it very difficult, if not almost impossible, in a large town like Belfast, to get milk suitable for an infant, considering the ill-ventilated byres in which so many cows are kept, and the feeding which they get; he therefore agreed with Dr. Wales as to the superior excellence of Swiss condensed milk. He had used it with admirable results. It had one special advantage in that it was not liable to the acid changes which so commonly take place in cow's milk. Dr. Dempsey had quoted a remark of Dr. Pavy, to the effect that children fed on Swiss milk, though thriving well for a time, were liable to succumb to the first attack of serious disease. Now he (Dr. Core) had seen such children come well through serious disease.

One case he remembered, especially from its apparent hopelessness at first, of an infant born prematurely, with whom nothing agreed—it was, in fact, dying. It was tried with Swiss milk, immediately began to thrive, and (though never robust) continued to do so. It afterwards came well through several attacks of exhausting disease. As to wet-nursing, he agreed with Dr. Dempsey in disliking it. The social and moral questions involved, the injustice done in most cases to the nurse's own infant, and the exceeding trouble that, as a rule, wet-nurses gave in a house, made him much prefer bottle-feeding, either with good cow's milk or with Swiss milk. He mentioned, incidentally, that he had seen a child fed on Nestle's milk-food in whom slight rickety symptoms had afterwards occurred, and asked whether any other member had any similar experience.

DR. LINDSAY believed that cases of marasmus occurred simply from the way in which the cattle were often fed,

and considered it the duty of the medical attendant to see to it, in cases where children are bottle-fed, that the milk is pure.

DR. WORKMAN referred to some continental statistics, which proved that in the foundling hospitals the mortality was much greater where children were fed on the bottle than by wet nurses.

DR. ESLER said: Mr. President,—In a manufacturing community like Belfast, where so many thousands of the population are mill-workers, and many of these mill-workers mothers who must leave their children to be nursed by hand, it is alike important to the State—which puts a high value upon infantile life—and to the medical man, who, perhaps, puts upon it a higher estimate, that correct opinions should prevail, and, at the same time, be disseminated on this subject—of laying the foundation of a strong physical development for the next generation of men. In speaking on “the milk-feeding of infants,” I wish to refer first to one or two points in connexion with the natural food—the mother’s milk. A common practice prevails—and prevails extensively amongst the older nurses—that for a few days after birth the infant must be fed in order to keep it alive until the milk comes to the mother’s breast, hence, toast and water, milk and water, or sugar and water is thrust down the infant’s throat ad libitum; and in order to assist young humanity to get rid of this unnatural food, copious doses of castor-oil are administered at uncertain intervals. All this I hold to be wrong. I was very much struck with the practice of the native aboriginal tribes of Victoria, on several occasions, when I had ample opportunity of studying their habits. The pregnant female takes ill, the tribe halt on the march, the child is born, and, almost immediately, put to the breast; by the end of a day the mother, with her young infant swathed in a kangaroo’s skin, is ready to rejoin the tribe. Following the teachings of Nature, I have been insisting on all my patients adopting the same plan—as far as the child is concerned—putting it to the breast at once, preventing the nurse giving it either food or oil. The advantages are double—the child has learned to suck by the time the flow of milk comes to the mammæ, the breast-milk acts as a natural purgative, there is no flatulence, colic, or purging, and the mother is, in almost every case, saved from that stage known as milk-fever. It is sometimes impossible, and in other cases not advisable that the mother should feed her infant. Where such a calamity occurs, the question the medical man has to decide is, whether the infant should have a wet nurse or be fed by the bottle. The selection of a wet nurse in most instances simply means a change of position for the two infants—the mother’s own child is put upon the bottle, and the foster child on her breast. I have no hesitation in expressing my opinion that for the preservation of the life of a valuable child, I would certainly select a wet nurse; but the subject we have to deal with principally in this discussion is that of bottle

feeding by means of cow’s milk or other artificial food. Those of our number who are connected with children’s hospitals have ample opportunity of investigating this matter, and I think they will all agree with me in this statement—that multitudes of our infantile population are starved to death by over-feeding. I cannot better explain what I mean by this seemingly contradictory statement than by instancing a case which came before me only yesterday. One of that possibly (?) useful class of women who may be called baby-farmers, or nursing-mothers, brought a male child, aged four months, to hospital, with this history:—The child had been attended to by another woman until a month ago, when it was put in her charge; it was then rosy and healthy; she understood that it had got a quart of milk in the twenty-four hours. In order possibly to economise, her instructions were to give it a pint of milk daily, with plenty of arrowroot biscuits and sop. The child got diarrhœa, was wasting rapidly, and death stared us in the face. My instructions to the nurse were, to just continue her line of feeding if she wished to see the child in its grave at no distant date; but that if its life was desired she must discontinue all feeding on solids, put the child on a quart of pure milk daily, with just enough boiling water added to make it milk-warm.

There can be no doubt, I think, from all one sees in practice, apart from chemical explanations, that starch as a food is not suited to children before they get their teeth. Cow’s milk, and, if possible, milk from the same cow, with one-third water added to the average of the whole milking, with a little sugar of milk to make up for the natural deficiency in that ingredient, will be found in most oases to give satisfactory results for the first six months of infantile life.

Due attention must be paid to the state of the bottle and tubes. Where vomiting occurs it is generally the result of over-distension of the stomach. A diminution in the quantity given will rectify this, and in cases of acidity an alkali, such as the saccharated solution of lime, or, if indicated, magnesia may be prescribed and added to the milk.

Cases present themselves occasionally where, notwithstanding all care and attention, the child does not thrive on cow’s milk. I have seen nearly all the artificial substitutes for cow’s milk tried with varying success; but the most marked cases of benefit have resulted, in my experience, from prescribing Nestle’s milk food as an addition to the ordinary milk in those obscure cases of wasting which do not come under any distinct heading, and which gives the doctor so much trouble and the parents so much anxiety.

Where you have a good constitution to work upon, bottle-feeding on cow’s milk gives very general satisfaction; but where there is a delicate organism, or unfavourable surroundings, as in the crowded wards of the union workhouse, the best, apparent care and attention is not sufficient to keep a bottle-fed child in

life, especially in cold weather, where the natural heat of the mother's breast and bed are exchanged for the cold cot, and not very warm affection of the attendant nurse.

Our duty as advisers of the public weal, in this matter I hold to be, to acquire right principles for our guidance, and, when opportunity offers, to disseminate these principles among those who can carry them into practice, so that at the same time the nurse may be instructed, the child's life saved, and our wisdom and reputation as preservers of human life placed in such a position, in connexion with the feeding of infants, that we may be recognised to be—what, indeed, medical men as a profession in a most eminent degree are—benefactors to our race.

Upon the motion of the Honorary Secretary the debate was adjourned for a fortnight.

Alexander Harkin, President

Third Meeting held in Hospital December 17th 1878

Present, Dr. Harkin, John Moore, Dempsey, Core, Fagan, Clarke, Wadsworth, Riddell, Workman, Esler, Whitla, Professor Dill.

Dr. John Rea was unanimously elected a member of the Society.

Dr. Whitla opened the discussion upon the milk feeding of infants. Dr. John Moore followed and Dr. Fagan. The President replied.

Paper:¹ DR. WHITLA said: Mr. President and Gentlemen,—My name appears upon the paper this evening as re-opening this discussion, but the announcement is merely a formal one, as it would be unpardonable for me to detain the Society with remarks upon a subject which is simply a matter of experience. In listening to the remarks at last meeting I was struck with their apparent diversity, and I believe this arises simply from the angle at which each one looks at the matter, not from any real difference of opinion.

All are agreed that a healthy mother's milk as food for her offspring cannot be improved upon—all, I believe, will agree that leaving out the moral objections to wet-nursing, and the objections of expense and expediency, that it is the best substitute, and it is only in cases where these two supplies fail us that we have now to consider the best course to pursue. For obvious reasons the milk of the cow is the pabulum nearly universally selected, and the question of dilution of this fluid is one which it is an utter impossibility to settle by any fixed rule. Our President strongly objects to the addition of water on the ground mainly that it has got enough already before it reaches the nursery, and I have no doubt that generally he is correct. My own limited experience in the Children's Hospital has thoroughly satisfied me that children are starved to death

upon milk and water in Belfast. If the question is put to me—would I give milk from the cow to a young infant, I would answer that this would entirely depend upon the feeding of the animal.

Not long since I ordered the pure milk of a fine cow brought from the country by a gentleman in Belfast very anxious to procure pure nourishment for his infant which was four weeks old. The result was near being disastrous, the motions became as firm as cheese, and the child began to sink from starvation of a worse kind than that so eloquently painted by our President. I was then forced to do what should have been my first duty—to inquire and see the cow's food, which I found was the best meal and potatoes, and also to have her daily produce measured, which was only nine quarts. The same cow had a week previously given nearly twenty quarts when fed upon boiled turnips.

This, gentlemen, is no exceptional case—it is the rule, and this fluctuation is what physiology would lead us to expect. Some affirm that though the quantity of milk produced by a cow changes wonderfully on altering her rations, still, they say, the quality remains steady. This I do not at all believe, as I have myself in the country and within the last month in Belfast proved. It is, however, a fact that the character of the milk will also depend upon the cow to an extent totally independent of feeding; and I do not profess to be a cow-fancier, but there is to my mind no cow like a thorough-bred Devonshire for raising strong and vigorous infants. Dr. McConnell stated his experience in the Union, which is of great value, and I believe his position about this question of dilution is the only truly safe one—that is, “to adopt no rule, but judge solely by the quality of the milk when you do not know the food which the animal consumes,” and dilute or not as the case requires.

I believe the practice of diluting the weak milk of cows forced by soft and watery foods, as is the rule in Belfast, has led to many fatal results; and we owe to our President a great debt for bringing the matter so ably and prominently before the Society. One word about the temperature of the milk. This I believe to be of the same importance as the temperature of the air breathed by the infant. Provision is made for variations of nearly 100°, and I think it is a matter of no practical moment whether it be 50° or 100° with a healthy child.

In conclusion, allow me to refer to a class of cases where cow's milk—no matter how pure or well selected—fails to nourish, and we are driven to a further extremity. Every one has met such. It is in these cases that attempts to utilise the teachings of the science of chemistry have resulted, I believe, always in increasing the number of pages in the Registrar-General's Returns; and if there be an example of the truth of Pope's line, “A little learning is a dangerous thing,” surely it is in the feeding of infants upon purely chemical principles.

What are we to do in such a case? My practice has

¹ [Dublin Journal of Medical Science, 1879, v67, p340.]

always been, where I could prevail upon the hearty co-operation of the parent, to resort to beef. Good cow's muscle, under-cooked, sucked to rags by the infant, never fails to sustain life where life is possible, and within these last two years I recommend it to all children. At present I am trying a modification of this practice suggested by Dr. Beck, senior. He recommends strong beef-tea, half a pint, one well-beaten-up egg, and half a pint of milk. As far as I can see it is an invaluable plan where cow's milk fails.

Dr. Core has asked for some information about Nestle's food. It is the only artificial food of which I have any experience, and I have seen splendid results from it. The great objection to its use is its expense. I have seen a strong infant eat twelve shillings worth per week, and this puts it beyond the reach of the poor.

One speaker referred to the infant mortality from a national point of view, and I feel I would not be fulfilling my duty as a physician, and as an humble unit in this vast empire, without seizing this opportunity of stating that the wholesale slaughter-houses in our midst should be under Government supervision. I refer to the system of nursing the children of mill-workers, and the nursing out of illegitimate infants. The Government has started a cumbrous and expensive machinery for watching the exact number of minutes per week each able-bodied operative will be allowed to work, lest the race should deteriorate, while the infants of these men are half-starved, and dwarfed to a degree which hardly anyone could believe without visiting the extern wards of the children's hospitals. And I often feel, while looking at their pinched and weird faces, that their cry for Government protection should be heard before that of lunatics, monomaniacs, and others.

Dr. JOHN MOORE said he should like to know the exact amount of milk considered necessary for an infant. He detailed a case showing the remarkable change which supervened upon the admission into gaol of a woman and her child, after she had given it her undivided attention. He long held that the State should interfere, and agreed with the Secretary that the question was a momentous one. He detailed another case where the child was buried alive, discovered, and taken to prison with the mother, and afterwards left there—as fine a specimen of humanity as he had ever seen. He advocated that women in the last months of pregnancy, and nursing mothers, should be excluded from public work; and he argued that it would be cheaper for the State to support both. He also thought that the food of the cow was of vital importance in the rearing of infants upon the bottle.

DR. HARKIN.—Gentlemen, the discussion evoked by the nature of my Introductory Address has been the source of much satisfaction to me, having called forth an amount of practical statements and observations of a most valuable character, based, as they were, upon the personal experience of the individual speakers.

I cannot regret that the debate should have taken a wider range than I anticipated, or that it should have assumed the form of a general disquisition upon infantile nutrition and the varied aliments and modes of feeding practised and recommended in this country; for, incidentally, much information has been elicited, and further proof has been given, if any were required, that the medical men whom I have the honour of addressing are not obnoxious to the charge of being merely the slaves of routine, then a subject of such vital importance is before them. My friend, Dr. Wales, who initiated the debate, among other sound remarks, stated as his opinion “that milk, as ordinarily sold, requires no dilution; but that he would not venture on ordering undiluted milk to a new-born baby.” In both these propositions he and I agree, for I should not think of recommending milk alone until at least two weeks had passed over, and until the integrity of the infant's digestive organs had been fully established. He says, further, “I cannot think it wrong to reduce the proportion of casein and salts in the cow's milk to those existing in human milk, by the addition of water, and of lime-water also, if disposed to acidity, with the object of preventing the formation of coagula, which often give rise to cholera infantum.” While, however, I accept his endorsement of my proposal, I cannot do so for the reasons assigned by him, as I have had, too often, sad experience of the persistence of infantile diarrhoea, until every, even the smallest, portion of milk was eliminated from the dietary of the suffering child. In this statement the high authority of the late Dr. Graves will sustain me; for in his “Clinical Medicine,” edited by Neligan, Vol. II., page 583, he says:—“It is incredible how small a proportion of milk, even in the most diluted state, will keep up this disease, acting like a species of poison on the intestinal mucous surface. You know that animal poisons, such as the variolous or vaccine virus, will affect the system, even when applied in a state of extreme dilution, and you can, therefore, conceive that a small portion of milk will operate in this manner.” I wish, however, to corroborate, to the fullest extent, all the commendation which Dr. Wales has given to the use of the condensed Swiss milk. I have had, in many instances, the greatest satisfaction from its use. In one remarkable case, wherein the breast milk of as many as seven hired nurses disagreed, and where the child's digestive organs were quite intolerant of cow's milk, from the first dose of the Swiss milk all trouble ceased—the child slept calmly, content spread over its features, the alvine discharges, previously most offensive, became natural—a change which I attributed to the elimination of the casein from the condensed milk, during the process of preparation. I saw this infant some two years after, and she had grown into a healthy, well-proportioned child, and had just passed unharmed through a severe attack of measles. So much for Dr. Pavy's theory. Professor Dill, in a statement replete

with information, among other matters, stated that he would dilute the milk with a little water, and that as the mother's milk grows stronger as the child grows older, he would, following the example of nature, decrease the ratio of dilution as the child advances. He gives the preference to asses' milk. We must remember, however, that, according to Playfair, asses' milk, although containing as much sugar as cows' milk, is too poor in casein and butter for the feeding of infants. Dr. Dill announces his strong preference for wet-nursing in contradistinction to bottle-feeding, and in this sentiment I quite concur.

Dr. Dempsey would dilute with one-third of water, with the addition of a little sugar of milk, and gives very judicious advice as to the care required in bottle-feeding. He attributes the dyspepsia and marasmus of hand-fed children more to the carelessness of those who feed them than to the dilution of the milk itself. I cannot assent to this theory; and Ancell on Tuberculosis, in a chapter on Diet, page 703, is also of a different opinion. He says, referring to children:—"I am practically convinced that habitual excessive dilution is very injurious in tubercular habits. I believe it assists to diminish the vitality of the blood and the number of the red corpuscles, to render the blastema and liquor sanguinis, less nutritive, and to deteriorate the cells and weaken the fibres." He gives also the case of an infant, three months old, in a very advanced stage of marasmus, which completely recovered on goat's milk. "It had nothing but the breast of one and the same goat for five months, and is now a perfectly healthy child." Thus we find that excessive dilution on one hand deteriorates the blood, and that pure unmixed milk is the remedy for marasmus. Dr. Dempsey condemns very strongly the too early administration of farinaceous food, but says that if any other than milk food is suitable for early infancy, the only one he can recommend is that prepared by Liebig. We must not forget, however, that, although Dr. Playfair joins in the recommendation, its use has been condemned by the Academy of Medicine in Paris, after being discussed at several sittings. We cannot, therefore, acquiesce in its suitability until the difference of opinion which exists be settled by an independent examination, by some medical tribunal in this country. Dr. Walton Browne would dilute with barley water one-third, up to the ninth month. Dr. Riddell's experience quite agreed with that of the President. Dr. Lindsay very properly insists that, when children are bottle-fed, the medical man should see that the milk be pure, and given by cattle themselves healthy; and Ancell, page 701, appears of the same opinion. He says:—"I have seen an infant deprived of its mother's milk, because she was of a tuberculous habit, and fed upon the milk of a cow which died of consumption. The child died of tubercles in almost all of the internal organs. The frequency of this disease in cows is a notorious fact. Dr. Workman showed by statistics that the mortality in

foundling Continental hospitals is greater in bottle-fed than in nurse-fed infants. Dr. Core believed that a great evil arose from people trying to improve on the proportion of nutriment given by the Creator. He strongly disapproved of wet-nursing of children. Milk, as sold in Belfast, did not require any further dilution. Dr. Esler disapproved of a practice common among the older nurses of feeding the infant before putting it to the breast, and instanced the case of the aboriginal tribes of Victoria, where the infant is put at once to the mother's breast after the birth is completed. He believed that multitudes of our infant population are starved to death by over-feeding. He would recommend the addition of one-third water till the sixth month of infantile life. He approved of Nestle's food. It is, no doubt, true that, in many instances, children are over-fed before the free secretion of milk appears; but the opposite evil is, in my experience, of more frequent occurrence. Mothers and nurses imagine that the turgescence of the breasts is a proof of the presence of milk, and many an unfortunate baby is compelled to tug and strain at a breast quite innocent of lacteal secretion. The infant starving, sometimes to the very verge of inanition, and often only saved by (I speak of my own experience) the free administration of wine-whey and milk. I do not consider the case of the Indian woman who, as a rule, is able to suckle her child for three or four years, at all analogous to that of the European mother, subject to all the depressing influences of modern civilisation. Dr. Whitla, in a well-reasoned article, among other remarks, states that his experience in the Children's Hospital has thoroughly satisfied him that children are starved to death upon milk and water in Belfast; and if he were asked the question would he give the milk from the cow to a young infant, he would answer—this would entirely depend on the feeding of the animal; and he gives a typical case in which the pure milk of a cow disagreed with a baby, the animal having been fed upon stimulating farinaceous food—food fitted only, in my mind, for a human being, the animal being denied the natural food of a gramivorous creature. I can, however, point to a child, now six months old, fed entirely, for many months past, on the milk of a Kerry cow, whose sole food is to be found in the grass of the field, and no better example of a rosy, thriving child could be found; and besides to many others in town and country, who have not had any other nourishment but the undiluted milk direct from the cow—the nature of the food, as the Doctor suggests, making all the difference possible in the nature and composition of the milk. McConnell diluted, but in regulated proportion to the individual case, not on any preconceived idea, healthy and unhealthy children requiring special provisions. He could not tell the proportion of water in the milk supplied to the workhouse, as he did not believe in the existence of any infallible test, and was guided chiefly by its taste and appearance. It is, however, a matter of

vital importance to look after the composition of the milk delivered to workhouses, as it enters into the diet of children, and old persons, too, in workhouses as a most important element. Mr. Wanklyn found that of fifty-seven samples of workhouse milk only three were up to the terms of the contract. Most of them had been deprived of a large portion of the cream and diluted with water to a serious extent. (See *British Medical Journal* January 27, 1872.) Dr. John Moore, from his experience, placed great dependence upon the undivided attention of the mother, and thought the Legislature should interfere to prevent the too speedy return of a young mother to work in a factory. The President agreed in both statements, and instanced the case of the town of Coventry, where it was feared that in consequence of the mills being closed in which the women worked at ribbon-making, caused by a change in fashion some years since, infant mortality would increase. It was found, on the contrary, that it had a marked decrease, proving that the maternal care given by mothers at home, through necessity, more than compensated for the better fare provided when the mothers were in employment and earning high wages. Dr. Fagan's experience coincided with that of Dr. Esler, and believed judicious starving useful in many cases. The President was of opinion that the children of the poor were not alone injudiciously, but also often overfed—even in their infancy partaking of the farinaceous and animal diet provided for their parents. The children of the well-to-do suffered from the opposite error, that of having to live upon milk diluted and barren of every nutritious material—the child, in many instances, seldom tasting milk except in tea or some other potation.

George F. Wales

Fourth Meeting January 7th 1879

Present, Dr. Wales Ex-President in the chair, Dr. Riddell, Esler, Core, Workman, Anderson, Wadsworth, Whitla, and many students.

Dr. Riddell read a paper upon "Croton Chloral and Amyl Nitrite with notes of several cases treated by these remedies".

Paper:¹ MR. PRESIDENT AND GENTLEMEN,—I thought it desirable to bring before the notice of this Society a few facts and experiences coming under my own notice concerning the medicinal properties of the so-called "Croton Chloral" and "Nitrite of Amyl." The literature of these drugs is not very extensive, but still sufficiently so to enable one to fill up the space of a long paper with notes and cases already reported. I have chosen another course, and prefer being brief and merely relating cases which have been under my own care, and which I have watched attentively. Neither can I enter into any dis-

cussion concerning their chemistry, nor concerning the physiological reasons of their peculiar actions on the diseased frame. I emphasise the word "diseased" for the reason that, as far as I have noticed, their actions in health and disease are quite different.

My first experience of croton chloral, as it is wrongly called, was in the person of a near relative, who for years had suffered from severe attacks of headache—so severe that at the times of attack she was quite prostrated. The constant description she gave to the medical men she consulted was that of feeling as if an iron band were round her head and crushing it. These attacks were recognised by all as neuralgic in origin, and for years it was attacked by all the "great guns" of the Pharmacopœia until its resources were exhausted—the bromides were tried up to so-called "heroic" doses; chloride of ammonium, iron, arsenic, hydrobromic acid, sedatives and stimulants; quinine, in small or large doses, only made it worse—all of no effect for good. I was reading some remarks in *The Practitioner* concerning croton chloral, and it seemed to me that it might do good in this case. I suggested it to her, and she consented to take it, but with no idea or hope of any relief, for she had suffered from these attacks for more than twelve years. I began with 5-grain doses twice daily and 10 grains going to bed, dissolved in spirits of wine and glycerine, with a little acid and syrup of orange to cover the flavour. The good effect of the drug was seen at once; the attacks came at longer intervals, and were less severe, then ceased altogether; and now for upwards of seven months she has had only two attacks—one at a time of great mental distress, and one when she stopped taking the drug, about two months since, when she resumed taking it, and has not had an attack since. She now takes 5 grains per diem (generally at night), is hearty and well, and has a good appetite. Her age, I may say, is sixty-three. The 5-grain doses only caused a slight drowsiness, but the 10 grains at night, by relieving all pain, gave her a good night's rest—in fact, she now enjoys better health than she has done for years.

Since that time I have used it largely—sometimes failing, sometimes relieving—till, by keeping an account of all my cases, it began to dawn on me which were benefited by the drug. Since then the number of cases relieved (some permanently) has increased. These cases are—headache in females arising from mental distress; those cases of headache so frequent at the menopause—in fact, all those called neuralgic, except a few arising from internal mischief, are benefited, and, in many instances, cured. In that distressing species of neuralgia called *tic-douloureux* I have found it in many cases acting like a charm. Of course I do not include any arising from cranial or intercranial causes.

I have tried it in neuralgia of the ovaries, but no good resulted. In insomnia it is not so reliable as the hydrate, but in some cases where the loss of, or inability to, sleep

¹ [*Dublin Journal of Medical Science*, 1879, v67, p346.]

is accompanied by a weak or fatty heart, it is to be preferred, as it has no weakening effect on the central organ of the circulation. In one case of delirium tremens, where the circulation was very feeble, the combination of croton chloral with digitalis had a wonderful effect, and it seemed as if the drugs could be given together in much smaller doses, to produce the same results, than singly. In this I pushed it from 10 to 30 grains every three hours, with drachm and 2-drachm doses of the infusion of digitalis. In pain arising from caries of teeth I have found it useless in most cases, and in all inferior to Richardson's "tr. gelsemini" but in one case of a nervous young lady, by giving her two 10-grain doses I was able to extract a tooth next to painlessly, to her great satisfaction. You will notice in all these cases it is in affections of those parts supplied by the fifth pair of nerves that it is of most use; but, to be of service, you must give the drug in far larger doses than prescribed in the Pharmacopœia—for adults, 5 grains three or four times daily, gradually increasing if required; if stimulants are wanted, dissolve it in rectified spirit; if not, dissolve it in glycerine. In all cases complicated with hæmorrhoids, give glycerine. If anæmia exists, combine it with iron, or, which I believe better, arsenic; then gradually lessen the chloral. In all cases I have found it better to give it in solution than in powder or pill.

Since last meeting, when it was intended that I should have read these notes, some cases of great interest have come under my notice, in conjunction with my observation on the fact that croton chloral exerts most influence on painful affections of the superficial nerves of the face and its adjuncts. On the 18th December I was consulted by J. A., aged twenty, a striker in a smithy, for "something in his eye." I made careful examination, and could find nothing, although there was intense photophobia—tears streaming through the "clenched" eyelids. I dropped in atropia and counter-irritated his temples, which I have often seen doing good, but to no purpose. Another examination discovered a minute abrasion of the conjunctiva. I dropped in oil and atropia again, rubbing the extract of belladonna over the eyebrows; no effect. It struck me to try the chloral, seeing its power over these nerves, and it was most wonderful. I gave him 10 grains at once, and repeated that dose in an hour, when considerable relief was experienced. I repeated the 10 grains in two hours more and the pain was entirely gone, though for precaution's sake I gave him 5 grains every three hours for a day or two.

J. F., brush-maker, consulted me on the 21st for facial carbuncle. You all know the terrible pain suffered in that disease. To control that pain and give sleep I gave opium, Indian hemp, and the hydrate of chloral. Opium gave relief at first, then failed on account of stomach derangement. The other two were useless, or nearly so. Following out the same line of thought as in the former case, I gave the croton in 10-grain doses.

The effect was simply marvellous. Giving 10 grains every three hours, the disease went through its different stages, and very seldom would the patient have known of anything the matter from the sense of feeling.

The last case was a lady who has been under my care a long time, and who for months suffered from neuralgia, coming on at 12 o'clock, noon. In fact, she said (a little bow-stretching, you will say) "I can set my watch by the attack." Considering the periodicity, I gave arsenic, nux vomica, iron, and a whole array of tonics. I then (since last meeting) gave the chloral; and after two days she has had only one attack, and that a mild one.

I do not vaunt croton chloral as a specific—I do not believe in the term except in one instance—I do not compare it with, or fight its battle against, any other drug—no physician should have a "favourite" drug or prescription—but in my hands it has been useful in relieving pain, and I use it as I would any other instrument for good.

I have only one or two facts concerning nitrite of amyl to bring before you. The first case is that of a young married lady with menorrhagia, who, at the times of the catamenia, suffered from terrible headaches—always relieved, however, by hot spirits and water. She herself and her friends were desirous of some other remedial means than spirits. I came to the conclusion that the pain was anæmic in origin; and the nitrite of amyl possessing the dual power of increasing the heart's action and dilating the intercranial vessels, I thought it would do good; so I mixed the amyl with equal parts of eau-de-Cologne, and ordered her to use 5 or 6 drops of the mixture dropped on a handkerchief and inhaled by deep inhalations. It succeeded perfectly, and ever since she has never been without that combination—all other remedies used to put an end to that infliction having failed.

One night I was called out to see a case—a woman aged about fifty-four—"heart disease" the friends called it. When I arrived I saw at once it was a case of asthma. She was in a terrible paroxysm; leaning forward on her elbows, with flushed face and dilating nostrils, she was gasping for breath. I thought of the amyl, and fortunately had some with me. I poured out 5 drops on my hand, rubbing them over the palm, and held my hand to her mouth; when she had inhaled 10 drops she could breathe naturally. A course of arsenic effectually cured her.

J. L., a clog-maker, consulted me the day before Christmas, 1877. He suffered from asthma, and the attacks were so frequent that he was off work more than half time, and the paroxysms were severe. In every case the amyl checked it at once; and now, nearly twelve months having passed, he informed me yesterday that he had only lost one week altogether, and that was through exposure to cold. I may say arsenic was the drug I gave him during the intervals.

I have had abundant opportunities of trying it in

sea-sickness, but only in a few instances it did good. But in that vile sickness one is thankful for small mercies. In one of my voyages one of the passengers had brought some chloroform on board for toothache. I was summoned in haste to her cabin, and found her quite insensible, pulse not perceptible, and evidently dying. Fortunately, though the nitrite was not in the ship's surgery, I had brought some to experiment with. After inhaling a few drops the heart's action was quickened and strengthened. Three or four times we had to repeat the inhalations before she was out of danger. It is so antagonistic to chloroform that I am of the opinion that it should be at hand at every operation in which chloroform is given. I throw out the hint for any of the surgical staff of the hospitals who may be present. In opium-poisoning I have derived no benefit from it—I suppose for the reason that that poison kills by stopping the respiration first. In fainting attacks from weakness of the heart, or brought on by witnessing an operation, or a cut, it is of great service. It has often an equally good effect in spasmodic and cardiac asthma, though its action must be different in the two diseases. In the one it must relieve by lessening the spasm of the air-vessels, in the other by increasing the power of the heart. How it does this I do not know; I am only glad to know that it is a fact.

In conclusion, I have brought before your notice what I believe to be two very valuable medicines, exercising relieving and curative effects on two distressing maladies—neuralgia and asthma, also acting as an antagonist to chloroform. If I can bring out of the more extended experiences of my confrères confirmation of my belief, my object shall have been gained.

DR. CORE said he had not used nitrite of amyl, and would hesitate to employ it while there still existed such grave differences of opinion about its dose and action. Upon the usefulness of croton chloral he would agree with Dr. Riddell if the fifth nerve only was affected.

Dr. ESLER thought with Dr. Core that the croton chloral was most useful and efficacious where the fifth nerve was in question. He had not used the amyl; he knew of so many hair-breadth escapes—and these acted to him as a beacon—he would wait for further light before employing it.

DR. WALES had used croton chloral a good deal; it was a favourite remedy with him in pain-relieving, but he never used it in the doses mentioned by Dr. Riddell. He would not go beyond 15 grains every two hours. He generally gave from 5 to 15 grains every twenty minutes, till three doses were taken, by which time he usually found the suffering diminish rapidly. As for the amyl, he never used it himself. He knew a medical friend who injected 15 minims hypodermically; the patient, however, died, but he did not believe the amyl had been the means; but it was an open question what effect such a large dose would have so quickly introduced into the circulation.

DR. RIDDELL said he mixed the nitrite of amyl with eau-de-Cologne, and allowed it to evaporate upon the palm of the hand while the patient inhaled its vapour. He would recommend that the croton chloral be always tested for starch by iodine, as he often found it so adulterated.

Dr. Whitla exhibited patients and showed microscopic specimens of Trichorexis or the so-called new disease of the hair, illustrating the subject by drawings etc.

Paper:¹ A discussion has been going on for some time in *The Lancet* and other medical journals under the name of "Piedra," and I notice that a lively interest is taken in it in England. Last summer M. Desenne described for the first time a condition of the hair found in the beards of the Columbians, and exhibited specimens before the Academy of Medicine. The diseased or affected hairs were seen to have distinct nodosities at intervals upon their shafts like so many small beads, but which were fixed to the hair, and in some cases only surrounding the shaft partially. The peculiarity of the nodosities, which distinguish them from growths at all approaching them in microscopic or naked-eye characters, is a very remarkable one. They will scratch glass by reason of their stony hardness; and when a bunch of the affected hair is struck against any hard surface a distinct ring is heard. M. Desenne found satisfactory evidence of spores, and concluded that the disease was evidently parasitic. A short account of his paper appeared in *The Lancet* of August 3rd, 1878, under the heading "A New Parasitic Disease of the Hair."

It is not my intention to detain you with any remarks upon this singular and rare disease, which is, as far as I know, peculiar to Columbia, and has only been examined by a fortunate few, who are by no means at one about its pathology. The notice of M. Desenne's paper was the signal for many observers to write—some agreeing, some pointing out differences in their observations; and, upon a careful perusal of the recent literature of the subject, there can be no doubt whatever that the English observers describe a totally different affection which has been for many years recognised in this country by a few. It is of this second condition, called by many names, such as "Trichorexis Nodosa," "Fragilitas Crinium," and "Clastothrix," &c., that the specimens exhibited under the microscope are examples. I noticed it about six years ago, and found its histological characters so beautiful and regular that I have watched for it and examined many such specimens. The first published account of it that I am aware of is from the pen of Erasmus Wilson, in the early edition of his work upon "The Healthy Skin," where, as early as 1849, he described accurately this state of the hair. In 1855, Beigel independently studied the disease,

¹ [Dublin Journal of Medical Science, 1879, v67, p104.]

as he called it, of “bursting of the hair.” In 1857, Dr. Wilks, in his lectures on “Pathological Anatomy,” figured and described the state of the hairs; and later, Tilbury Fox, under the head of “Sycosis,” figured a similar state of matters, plus a graphic drawing of sporules mixed up with the fibres. A few other published references to the subject may be found, but its history and literature are ably and exhaustively recorded in *The Lancet* of December 7th, 1878, by Dr. Thomas Fox, Physician to St. George’s Hospital—who, by the way, quotes Dr. H. S. Purdon as describing an affection which he was not at the time referring to.

Now, as regards the condition or affection, or “disease,” as it has been called, its naked-eye characters vary slightly in differently coloured hairs, and I may say here that it is solely to specimens taken from the hair of the face that my remarks refer. The hairs affected are marked at irregular intervals with white transverse bands, which thus resemble somewhat minute porcupine’s quills. The band is of a pure clear white in the hairs of an amber colour; in the long dry and fine hairs, seen in dark reddish-brown beards, these transverse markings have a dirty white or translucent hue, which often renders them difficult of detection. These bands, or white transverse striæ, have been called nodes by most observers, who describe them as if the swellings of the hair which constitute them were quite perceptible to the naked eye. Such is hardly correct, as in most cases no one could possibly recognise them as swellings till under the microscope—persons with very sharp sight might sometimes.

The hairs breaking off generally at one of these nodes possess thereby another peculiar appearance—their ends seem white and abrupt, just as if they had been burned, and once I was consulted by a gentleman for this state of the hair whose family physician persisted in telling him that his beard was “singd.” There may be only one white mark on a single hair, or there may be twenty. This latter condition is very rare, and the number of nodes seem to depend greatly upon, the coarseness or fineness of the shafts. The strong thick hairs of curly beards and whiskers break off short at these nodal spots, and seldom show more than six upon the stump of the shaft remaining, while the finer sorts of hair, which are straighter, do not give way so readily, and upon one patient’s beard, which I will exhibit to you, you will find hairs eight inches long, with from six to eighteen nodes visible to the naked eye. His case is exceptional, however. As to the situation of these markings on the shaft, I have seen one upon a long hair within one-third of an inch from the follicle, the remaining part quite normal. I have also seen one nearly as close to the free end in a similarly healthy shaft; between these two are all possibly divided conditions. The shaft is frequently bent at the node, the angle formed being always a sharp one—in very curly hairs it may be acute. There is not much bending (sometimes

not any) at the junctions of the nodes in long, straight, fine hairs.

The microscopic characters of the affected hairs are very striking, as you will see by the accompanying diagrams and under the different microscopes upon the table. The fibres of the cortex of the shaft are frayed out in a beautiful manner at the node. The hair seems just ready, as it were, to break into two distinct pieces through the centre of the swellings, as many of the circumferential fibres are entirely separated. The diagram which I draw of the appearance seen under instrument marked No. 1, you will observe, is almost a facsimile of Mr. Wilks’ woodcut in the number of *The Lancet* on the table. The appearance perfectly resembles two blunt camel’s hair pencils placed end to end, and gently pressed against each other so as to cause the hairs at the circumference to bulge out freely. The medulla is seen in No. 2 to be absent entirely, but under the next instrument you will observe a node just in the act of forming. The specimen proves the error of a very eminent observer, who denies that there is any swelling prior to the fraying out of the fibres. Here the diameter of the shaft is unmistakably increased. Only a few small fibres have started out on each side of the node, the soft cells of the pith are much increased in number, and the pigment is scanty. Under another instrument you will see a young node, which, however, is perfectly formed; the small, bright, scale-like particles inside the long frayed-out fibre are, I believe, the pith-cells which have dried up to some extent and are adhering to the inner surfaces of the fibres, possibly showing the reason of the varying quantity of the medulla, as noticed by Dr. Thomas Fox and Kaposi—the drying process probably commencing when the outer fibres burst open. Pigment varies; as a rule you see scarcely any in the outer layers of fibres, and seldom any in the central part, occupied by the medulla, in the node. Air cavities are seen, but only rarely, in the medulla of the shaft at a distance from the break, but sometimes they are found near to it, and, on close examination, you will find this is owing to the consequent drying of the soft cells or the mechanical separation of the harder ones. Some of these hairs are in every other respect normal and perfectly developed, others again are badly formed, stunted, devoid of epithelium, and brittle; at the same time hairs of this latter class are found with all these imperfections, but without any trace of the characteristic nodes. I cannot see any departure from the normal state in the root-sheath. As regards longitudinal splitting, associated with trichorexis nodosa by some observers, I have frequently seen it, but as often in sound hairs as in those affected with the transverse markings. I have never been able to see any evidence of parasitic disease, and the different specimens before the Society are devoid of any resemblance to spores.

The most interesting feature in connexion with this state of the hair is its distribution, and it is to this

point I wish particularly to direct the attention of the Society. I have failed to find it in about half a dozen men whom I have imperfectly examined, and whom I only saw either in a bad light, or rather hurriedly. I am almost certain it is there, but cannot state it is positively. I have failed to find it once when I had every facility and sufficient time, and spared no trouble in searching. If you permit me to make this solitary exception, I say I have seen it in 200 or 300 men whom I have examined, and I believe within certain ages the distribution of these characteristically marked hairs is as universal as the growth of hair itself. The specimens upon the table are each, as you will see, from the office-bearers of the Society, whom I had an opportunity of examining during the last week, beginning with the President. The single exception above referred to was in the case of the Treasurer, who has the most perfectly formed beard to be found, and his case abundantly proves the rule. After a search I came upon a doubtful hair, and placed it under the microscope; it had no characteristic markings, but, what was to me more interesting, a distinct though very small swelling at one portion of the shaft, with two fibres frayed out, as you see in this drawing on the black board, and its owner was convinced that this was the first step in the process of bursting; it was not, however, anything like so evident as the specimen under No. 3. If this be an affected hair, then I have not seen a beard where I have carefully examined and failed. In all doubtful cases the hairs are tested under the microscope. I examined a chemist three times carefully and failed to find a single hair affected, and he was put down as the only exception I had then met with. He had most exuberant growth of beautiful whiskers. I met him a short time ago; he had got his whiskers closely trimmed. He readily consented to re-examination.

The long flowing hairs were not in my way now, and I soon pounced upon two beautiful specimens, one of which is under No. 5; these were the only hairs affected, I believe, upon his entire face. One other case, and we have done with this part of the subject. I sent, some time ago, a few hairs to a celebrated histologist. He examined them, and concluded that the alterations were the result of chemical changes produced by hair-dye. When I next met him I told him I had been finding them in everybody. He seemed much amused, and, when I suggested the possibility of their being in his own beard, he laughed outright. "He had examined it often for other purposes," but upon importuning him I was permitted to look, and found them in thousands. I mention this to show how they may be overlooked unless specially hunted for—the gentleman referred to being the most accurate and gifted observer that it has ever been my good fortune to meet. They will be found studded thinly over the entire beard. This is uncommon. You will often see them in patches as large as a crown. Their most common site is just under the lobule

of the ear. Another very favourite situation is over the region of the depressor anguli oris muscle. They are very seldom found in the much-twisted and incessantly-pulled mustachios of young men. I have only met with them there once or twice. I have seen them in gray-haired men of sixty-six and in boys of twenty. It has never been my lot to find them in the hair of the scalp or on that of any other region of the body.

The rarest class of cases is that where the hairs of the face seem all affected uniformly, and this is the only way in which I can imagine that the matter has been spoken of as being so rare and unusual. Of the last class of patients I have only seen two well-marked cases—one of whom I now show you. He is the owner of an extensive bread-baking concern, and has kindly consented to show himself. You observe the general character of his beard; it is long, straight, red in colour, and surprisingly dry. You feel it and you almost think you are grasping some dry flax, and he tells me he washes himself every morning, beard included, with several lathers of soap, and dries with a coarse towel. He certainly seems to favour the idea that this is a mechanical process operating upon dry hairs. But, upon the other hand, look at these beards round the table shining—some of them even glistening with sebaceous material; they also show the same state of matters to a less extent. Some of these dry hairs are under the last instrument; they in no way, that we can see, differ from those of the chemist's case. I regret to say that I have not yet been able to have an examination of the hairs upon this patient's pubis. A peculiar feature I have noticed in those cases where the affected hairs are found in patches is a sense of burning itchiness, or even smarting, experienced in the patches at times, especially when the face is flushed. This, at one time, led me to think that some irritation might be going on in the hair follicles, and the presence of the entozoon folliculorum suggested itself to me, but I could not satisfy myself that it had any connexion with it, and I have not been able to transplant the animal to the pubic region.

This brings us to the pathology of the subject, and it is possible that we have something still to learn as to the cause of this singular state of the hair. When I first saw it the idea of mechanical twisting being the rationale seemed obvious, and I marked certain hairs close to the affected ones upon my own face, and pulled at them for a few weeks without producing any effect whatever. This, with the fact of their being so rare in the hair upon the lip, satisfied me that torsion had nothing to answer for. One of the specimens upon the table would at first sight lead you to believe that this theory was correct. Here a transverse cleavage has not yet occurred, but the shaft of the hair is bent round like the arch of a bridge; upon the convex surface, where the greatest strain would be, the fibres have sprung out, as if ruptured by the bending. That this is not the beginning of the process, you have only to look at the concave

side, and, though you find no frayed-out fibre-cells, you will see a distinct preliminary bulging, owing to the proliferation of the cells of the medulla. What has occurred is evidently as in No. 3, and if you suppose the specimen there bent at the enlargement you would have this condition precisely repeated, showing that the bending is simply secondary to the swelling and consequent weakening of the shaft at that place.

Beigel states that the breaking is caused by the expansion of air imprisoned in the shaft which, finding no egress, bursts the fibres of the cortex. This could only, however, occur as the result of an explosion, for, suppose one fibre gave way, a chink would be formed and the imprisoned air would escape; and, indeed, I see no reason whatever for supposing air acts in any way inside the cylinder.

I say this without hesitation, though against so distinguished an authority, because the idea presented itself to my own mind long before I had heard of his publication, and I had also discarded it. It has been suggested that altered nutrition, caused by affection of the trophic nerves, as in alopecia areata, would explain this; but it is hardly possible to apply this explanation to cases where only a few isolated hairs are found in a healthy beard. The parasitic theory will not satisfy those who fail to see any evidence whatever of spores; and when you think of the beautiful sieve which the finely reticulating fibres of the cortex make, and consider that this sieve may remain open to every blast of air which blows upon the face, the wonder is that it does not exhibit from time to time quantities of living organisms.

The universal distribution of "trichorexis nodosa" suggests to me that it might, strictly speaking, have no pathology. Can we call a condition which is so general a "disease?" One is led to regard it rather as the result of some physiological action modified or varied perhaps in different individuals. I do not willingly submit another to the many explanations given by writers upon this subject; but the view I would lay before you is one which seems to me the most likely (that is all I can say for it), till some more satisfactory one is presented. It is this—that the outer fibre-cells of the cortex of the shaft of a growing hair, becoming hard and firm as do those of the nails, do not yield to the expansion of the inner quickly-growing soft cells of the medulla, and the result is their gradual separation and the disintegration of the cortex structure.

The specimens exhibited tend to support this. You have unmistakable evidence of a prior enlargement. Abnormal dryness may make these cells more prone to split up; and I found them more abundant in the cleanly, who freely use soap and water, than in those who pay no attention to their personal appearance; but why the cells should split up in a patch upon one side of the face and remain normal on the other, is not easily explained. There is no state of the system which I could

notice that favours their appearance. They do not seem to be at all influenced by the broken-down health consequent upon recovering from typhoid and other fevers or lingering diseases. They will be found in the weak and robust, the young and the old, the vegetarian and the gourmand, the teetotaler and the drunkard.

[The discussion below is not in the minute book.]

Paper:¹ Remarks upon DR. WHITLA'S Specimens of Trichortxis Nodosa, exhibited at last meeting.

Dr. Core had read the discussion, or rather series of letters, in *The Lancet* with interest, and he thought that three different diseases were there referred to—one, the Columbian, then a parasitic, and, thirdly, the one demonstrated by the Hon. Secretary. The subject, he thought, was one of great interest, especially as to its wide distribution. He did not believe the specimens were or could be mistaken for parasitic disease.

Dr. WORKMAN, who had examined very many specimens with Dr. Whitla, could corroborate his statements in every particular. The cause was obscure, but he did not believe in the parasitic theory. Many of the hairs he noticed were split longitudinally, but only at the ends.

Dr. ANDERSON thought that the pathology of the condition was simply a change of nutrition in the root sheath, and he proceeded to support this view by a reference to the growth of the nails, likening the nodes to the white specks seen in these appendages, and to the ridges and irregularities seen in cases of recovery after fevers, &c.

DR. RIDDELL did not see that the subject was one of much interest, or that there was much mystery about it. The hairs seemed broken simply from combing, twisting, and pulling. He had not noticed any hairs like those spoken of in the natives of Australia, and he consequently thought that it must be caused by the use of the comb. He thought that simple bending and brushing might do all that was described—he saw no reason why it should not.

Dr. ESLER thought that Dr. Whitla had clearly demonstrated to him that this was no mere mechanical breakage, and, after examining the specimens upon the table, he thought it impossible to conceive this, nor did he believe it was parasitic.

DR. WALES said the subject was new to him, and he had looked at the microscopic specimens with care and they surprised him. He thought the distribution of the condition a most important point; it proved that it could not be regarded as a disease. He had taken some hairs from the beards of the patients exhibited, and he would examine them with interest.

Dr. WHITLA said he had at first taken every pains to satisfy himself about the mechanical theory. He marked hairs upon the margins of his own face, and found that

¹ [Dublin Journal of Medical Science, 1879, v67, p350.]

twisting, bending, and pulling to an extent far beyond what would be applied ordinarily, produced not the slightest effect. The favourite sites of the affected hairs were not those subjected to friction. He had tried the effects of torsion and bending upon wet hairs, warmed hairs, and very dry ones, without any result. Those who believed in this as the cause always supposed that in order to break, the hairs must be previously diseased—morbidly dry. He was satisfied that three different conditions were described, but was inclined to think that the presence of spores was not the cause in those cases observed in the nodes, for it was clear that the characteristic breaks could be caused independent of them. Several who had written upon the subject—and eminent authorities upon skin affections also—had spoken of seeing one, two, or three cases.

His experience of its almost universal distribution was his apology for bringing the matter before the Society; but he would say, to be always found they must often be most carefully and diligently hunted for in some beards.

Alexander Harkin

Fifth Meeting of the Society was held upon January 21st Tuesday 1879

Present, Dr. Harkin President, Dr. Wales Ex-President, Dr. Browne Vice-President, Dr. John Moore, Dr. Workman, Esler, Clements, Anderson, Dempsey, Mackenzie, Lindsay, D. Johnston, Whitla Honorary Secretary, O'Neill, and Clarke.

Dr. Esler read notes of a case of postpartum hæmorrhage treated by the injection of hot water.

Paper:¹ MR. President,—I bring this subject before the Society—1st, because of its great importance; 2nd, because it is a new method of treating a troublesome complication of labour; and 3rd, because I was amongst the first to try it in this country. The history of its introduction is given in a letter from Dr. Whitwell, of San Francisco, to Dr. Atthill, of Dublin, and is briefly as follows:—

In 1874–5 in the Women's Hospital, State of New York, hot water was injected into the uterus of a patient, from whom a sarcoma had been removed, with good effect. In August, 1875, Dr. Whitwell tried hot water injections in Breslau, and subsequently in Prague, with the best results, always causing quick and firm contraction of the womb.

Dr. Atthill, of Dublin, saw the account of these cases in an American journal; and in *The Lancet* of January 5th, 1878, published his first two cases. I had just read Dr. Atthill's article in the week after publication, when I was sent for to attend Mrs. B., a stout woman of thirty, in her third confinement. Her first child was born two and a-half years before, after which there was extens-

ive flooding. Twelve months after, her second child was born, when I saw her for the first time; there was detained placenta, which had to be removed; flooding supervened, which was treated with cold applications; the loss of blood was so great that recovery was considerably retarded. Her third confinement took place on the 12th January last year; the labour was normal; the pains were regular; but after the expulsion of the child and removal of the placenta, the uterus ceased to contract, the loss of blood was again very great, and was beginning to tell on her pulse; she became faint and blanched.

From her former experience she greatly feared the shock from the application of cold. I immediately procured a Higginson's syringe, passed the vaginal tube well into the uterus, and smartly injected half a basin-full of water at about 112°. Almost instantly the uterus contracted firmly, the hæmorrhage ceased, the pulse improved, and the patient expressed herself as feeling most comfortable, and the anxious countenance gave place to a placid calm. After the expulsion of some clots all went on well. During last Summer I met with two cases demanding more than the usual application of cold—one of them where a midwife thought the patient dying. I need not trouble you with details; the same means used brought about the desired results; and, from what I have seen, I have no doubt that hot water is one of the best agents we possess to cause safe and speedy contraction of the uterus. In each case I have been impressed with the rapidity with which the exhausted patient rallied, and with the expression of a feeling of comfort imparted by hot as compared with cold applications.

DR. WALES had no experience whatever of the injection of hot water, but if a case occurred in his practice he would have no objection to try it. He spoke very favourably of the injection of ergotin subcutaneously.

DR. LINDSAY thought that the case was very graphically painted by Dr. Esler, but he would be very slow to endorse the general use of hæmostatic remedies. In a very large practice of ten years he only met with four cases which he would call cases of post partum hæmorrhage, and he would like to hear Dr. Esler define what he meant by post partum hæmorrhage. He thought that many cases occurring with young practitioners were called cases of post partum hæmorrhage which were not.

Dr. D. JOHNSTONE had no experience of the hot water treatment, but any remedy which fulfilled the indications stated by Dr. Esler would be a welcome one. He would not be inclined to use water at a temperature of 110°; ice at all times responded to his call. He also found that the hand put in cold water and then introduced into the uterus and maintained there for a short time, had a very decidedly beneficial effect. He asked for an explanation of the way in which hot water was supposed to act.

¹ [Dublin Journal of Medical Science, 1879, v67, p352.]

DR. O'MALLEY had a good many cases, but he never had to resort to the hot water or to iron; his cases all yielded to cold water, applied externally, with the hypodermic injection of ether.

DR. BROWNE always used ice in bad cases, and never lost a patient. He commented upon Dr. O'Malley's case of ether as being the first in the North of Ireland.

DR. WORKMAN explained how the hot water caused the stoppage of hæmorrhage, and detailed the effects which he had observed by the application of hot water to frogs; he found it tetanised them by a powerful action upon the entire nervous system.

DR. JOHN MOORE thought that there may be difficulties in wandering away from old paths. One thing which, however, would speak loudly for this new treatment was the universality of the remedy; ice might be difficult to find, but hot water was everywhere; he never used it however. The mortality after delivery was much higher than most men imagined; he had satisfied himself that 1 in 150 was about the true figure. He detailed a case where he saved a life by pressure up on the aorta, and he reviewed other methods of treatment.

DR. CLEMENTS had a large experience as Registrar, and he would state that the mortality was not nearly so high as Dr. Moore stated; he only remembered one case being registered as caused by labour in some six hundred cases.

DR. HARKIN had not tried the hot water—he was perhaps too fond of sticking to the old ways. As regarded other methods of treatment, he reviewed them in detail, and said that when everything failed, “he put a cork in the bottle.” He seized the uterus with one hand firmly, introduced the other into the vagina, and so held it that it was impossible for one drop to escape, and in some cases he had to introduce a sponge in vinegar. If he found after a time that the pulse did not rise, and that on removing his hand a tendency to return occurred, he then injected ergotin, and it always succeeded. He detailed a case where he injected ether two and a-half years ago—the patient, however, died. He would hesitate to use hot water.

Dr. J. W. Browne showed a specimen of extra-capsular fracture of humerus, of fracture of femur, of a femur eroded by an aneurism of popliteal artery, 2 specimens of the os calcis removed for disease.

Paper:¹ DR. WALTON BROWNE exhibited two specimens of diseased os calcis, which he had removed in their entirety by excision. Both specimens had been removed from scrofulous subjects, and had taken on carious action, the exciting cause being an injury. He pointed out the various methods of excision of the bone as practised by Erichsen, Grau, Holmes, Buchanan, Hancock, and Greenshaw, and stated that he preferred Holmes' operation—Holmes' Surgery, Vol. III., p. 828. Dr.

Browne also mentioned Buchanan's idea, that when caries attacks the os calcis, it does not, as a rule, extend to the other bones of the tarsus, so that we are somewhat justified in recommending excision of the bones. He said that he did not approve of the gouging of a diseased os calcis; he had done so five or six times, the results being very unsatisfactory. He did not approve of Allier's subperiosteal excision, but advocated strongly Holmes' method, removing the entire bone, and its periosteum. One of his cases had terminated fatally five months after the operation, the cause of death being phthisis; in the other case, the boy had a fairly useful foot, being able to walk with the aid of a stick. Dr. Browne also mentioned that Mr. Tyrrell, of Dublin, had been the first surgeon in Ireland to excise the entire os calcis. He hoped to publish the case in full shortly.

DR. BROWNE also exhibited an extra-capsular fracture of the femur; also a femur which had become eroded upon its posterior and internal surfaces by the pressure of a popliteal aneurism.

DR. HARKIN thought that the specimens of os calcis were well worthy of recording, but he hardly thought that there was sufficient evidence before the profession to thoroughly establish the operation.

DR. WALES thought that a cast of the foot taken after the operation of excision of the os calcis would be a very interesting study.

DR. ANDERSON asked how long the aneurism had pressed upon the bone.

DR. WORKMAN saw in the Glasgow Infirmary two cases of excision of the os calcis, done by Dr. Buchanan. He believed it was a justifiable operation in suitable cases.

DR. MOORE said the old man who supplied the fracture of the humerus had received the injury upon 24th December last. It showed the effect of an injury to bone in a man so old—eighty-four years. As regarded the excisions about the ankle-joint, he thought too much importance could not be attached to the use of Esmarch's bandage. He detailed the objections to its use, which, he believed, were owing to imperfections in our application. He thought that the fracture of the femur was a complicated one, and that the neck was partly absorbed, he did not think that a fall against the wall would produce this break. It was a question whether the fall in some cases was not the result of the fracture. As regards the popliteal aneurism, he would remark that this form was rare here. He detailed a case where manual compression was used with a success which at first surprised him, but the patient sank from gangrene, he did not believe that the electrolytic method was of any use.

DR. ESLER thought that a lesson might be taken from these dry bones—fractures in old people ending often so fatally, while in the young they seemed to have so little to say to life's duration.

The PRESIDENT, in thanking Dr. Browne for his

¹ [Dublin Journal of Medical Science, 1879, v68, p176.]

interesting specimens, asked about the previous history of some of the patients.

Alexander Harkin

The Sixth Meeting February 11th 1879

Present, Dr. Harkin, Wales, Workman, Anderson, Fagan, McKenzie, Withers, O'Neill, Clements, John Rea, J. Browne, Dempsey, Esler, Dill, and Whitla, and many students.

Dr. Anderson showed the following specimens...

Paper:¹ 1. A beautiful specimen of talipes equinus, and demonstrated the altered directions of the articular surfaces of the bones, and the effects following these. New articular facets were to be seen. He considered the case one of the acquired variety.

He also showed—

2. A very interesting specimen of advanced rheumatoid arthritis of the hip-joint.
3. A case of exostosis of the great trochanter.
4. Rheumatic arthritis of the elbow-joint, showing the porcellaneous formation.
5. A deformed scapula, from mollities ossium.
6. An apparent fracture of the acromium, which has been described as a separation of the epiphyses, the surfaces being rough and irregular.
He spoke of its relation to rheumatic arthritis, and thought this explained the non-union. He supported this view by a study of the centres of ossification. Many of these cases were turning up in the rooms yearly.
7. Ditto. Dried specimen.
8. The bones and ligaments in an old-standing dislocation of the head of femur, associated with atrophy of the muscles, and great thinness of the bones, though the subject from which the specimen was taken was one of very active habits, and lived by spinning.
9. A beautiful specimen from the same subject, the thinned-out calvarium, where the bone was as thin as writing paper.
10. An impacted fracture of the articular surface of the tibia.
11. The calvarium, from a man who died from the effects of the inner table of the skull being broken. The specimen showed the great value which would have resulted from the use of the trephine.

DR. FAGAN thought that he would have had more inversion of the foot in the case of talipes equinus. He explained how the tibialis would have tended to draw in the foot, but, strange to say, there was no inversion. As regards the ununited epiphyses, he thought that these should not be mistaken for fracture. He referred to the opposite shoulder. It generally occurred double. As regarded the fracture of the tibia, he thought the specimen very interesting.

DR. BROWN had two cases of acquired talipes equinus from injury to the leg muscles, ending in diffuse cellulitis. He would have thought that there would have been inversion. He quoted from Dr. Hudson, who trephined all head fractures, and referred to Professor Goslin's authority.

PROFESSOR DILL commented upon the specimen of diseased pelvis, and explained how the disease upon the outside of the pelvis so affected the sacro-iliac joints as to cause difficulty in labour without interfering with the measurements of the pelvis.

Dr. J. W. Browne showed upon a model his method (Spence's) of treating fracture of the patella, and give cases.

He showed upon the model the objections to Maligne's hooks and other methods.

He showed Martin's elastic bandages for the treatment of varicose ulcer of the legs, and commented upon its action and detailed cases.

The Seventh Meeting February 25th 1879

Present, Dr. Harkin President (in the chair), Drs. Wales, Moore, Workman, Dempsey, Withers, Wadsworth, McKeown, Mckenzie, Dill.

Dr. McKeown exhibited a patient from whom he had removed a large nasal tumour through the antrum of Highmore.

Alexander Harkin M.D.

The Eighth Meeting of the Society March 11th 1879

Present, Dr. Harkin, Dr. Dill, Dempsey, O'Malley, Withers, Workman, Whitla.

Dr. Dempsey read a paper upon catarrhal pneumonic phthisis.

Paper:¹ Mr. President and Gentlemen,—Before reading the notes of my cases of catarrhal pneumonic phthisis, with your permission, I will briefly preface them with a general description of the disease.

Catarrhal phthisis is described by Dr. C. Theodore Williams as an affection of the lung, which may be clearly traced to catarrh of the bronchi, induced by cold or damp, creeping down into the alveoli, and thus originating catarrhal pneumonia, followed by implication of the alveolar wall. Niemeyer is of opinion that most cases of pulmonary phthisis have this origin, and he believes that those cases in which tubercles afterwards form have been preceded by catarrhal pneumonia and cheesy degeneration; and Virchow doubts whether there ever occurs an eruption of miliary tubercles without previous cheesy deposits in some part of the body. Pathologists are now pretty generally agreed on the catarrhal origin of a great many of the cases of pulmonary consumption, which hitherto would have been looked upon from the first as of tubercular nature.

¹ [Dublin Journal of Medical Science, 1879, v68, p175.]

¹ [Dublin Journal of Medical Science, 1880, v70, p348.]

The following is a general history of the sequence of events:—A patient who is weakened by some previous disease or privation, or who has a hereditary predisposition to phthisis, or who is scrofulous, or has been scrofulous, gets bronchial catarrh, with cough and expectoration, and after a variable time this becomes localised in some part of the lungs, and at the same time extends from the bronchi into the air cells.

Crepitus becomes mixed up with bronchial râles, expectoration becomes purulent, rusty, or streaked with blood, dulness is elicited on percussion, and with these signs there is an elevation of temperature, and as the disease progresses the symptoms become exactly similar to those usually described as characteristic of pulmonary consumption.

Single lobules only may at first be affected with this alveolar catarrh, but if the disease be not arrested, it may gradually invade the air cells of an entire lung.

In mild cases, and under favourable circumstances, the secretion may be expectorated without undergoing any change, or it may be partially expectorated and partially absorbed—fatty metamorphosis taking place in the cell contents, rendering them fluid, and in a state for absorption. But if the cell elements accumulate in the alveoli to such an extent as to exert pressure on the surrounding tissues and blood-vessels, destruction and death of the alveolar walls occur from want of nutrition. Softening and liquefaction of the degenerated products next occur, and a whole mass may be expectorated, leaving a cavity. In this way a lung may become completely riddled with cavities without tubercle taking any part in the process. But the irritation produced by the presence of the alveolar catarrh and the cheesy degeneration it results in, is supposed to have a local influence in the production of tubercle. Niemeyer suggested that this takes place through the lymphatics, and the researches of Drs. Burdon Sanderson and Klein on the minute lymphatic system of the lungs would seem to confirm his views. Dr. Powell describes a form of tubercle, the result of alveolar catarrh, which differs pathologically from miliary tuberculosis by its primarily attacking one portion of one or both lungs (almost always the apex), and spreading therefrom not by the dissemination of miliary tubercles far beyond the margin of advance, but by a continuous growth involving the destruction and subsequent excavation of the affected lung, and he applies to this affection the name chronic tubercular phthisis.

We should, therefore, look upon all cases of bronchial catarrh with suspicion, especially when it occurs in weakly or scrofulous individuals. By due attention to this catarrh—the “prodromal catarrh” of Niemeyer—we ought to be able to do a great deal in a preventive way to lessen the mortality from phthisis; and even when it has passed on to the advanced stages of the disease, there is still good hope of recovery if there have set in no tubercular complications.

The cases I will now relate were, I believe, of a purely catarrhal nature, and the results of treatment in all was most satisfactory.

CASE I.—Mrs. F., aged twenty-three, fair complexion, gave birth to first baby 29th Dec., 1876. Her convalescence was retarded by a pretty sharp attack of so-called “milk fever.” She nursed her baby, though she suffered severely from fissured nipples. About the middle of February she got a mammary abscess. Whilst attending her for the latter, she complained of a bad cold she had had for some time. I examined her chest, and found it studded over with moist bronchial râles. She was very weak, and had a bad appetite. I opened the abscess, and prescribed quinine and iron.

I next saw her on April 11th, about two months after I had lanced her breast. The cough had never left her; it was getting worse, and there was a great deal of thick expectoration, which some time ago was slightly tinged with blood. She had night sweats, was very weak, and had no appetite; her breathing was short, and she was losing flesh rapidly. There was a hectic flush on her cheeks. Pulse, 118; respirations, 28 in minute. Her father and mother were both living, and there was no family history of consumption. There was percussion dulness under left clavicle, and down to fourth rib, and over this area there was fine crepitation, with scattered subcrepitant râles. The posterior part of the same region revealed the same signs. The base of the lung was healthy; the right lung was also healthy. I painted a blister under the clavicle, and prescribed a mixture of Parrish’s and Easton’s syrups, and directed her to wean the child at once.

20th.—Pulse, 110; appetite better; signs much the same as on last visit. I ordered her cod-liver oil, and directed the affected area to be painted with iodine.

26th.—Pulse, 98; cough very troublesome, and prevents her sleeping at night; night sweats somewhat diminished. Prescribed a morphia and chlorodyne cough mixture. To take Parrish’s syrup alone.

May 3rd.—Pulse, 84; feels stronger; the cough and night sweats very much diminished. The crepitation is now replaced by moist subcrepitant râles, and dulness on percussion is not so marked.

21st.—Pulse, 76; coughs scarcely any; can eat well; percussion note almost as clear as on opposite side. The healthy vesicular murmur is heard all over the apex in ordinary respiration, but on deep breathing some scattered, dry, creaking sounds are heard. Night sweats have entirely ceased. She has gained flesh, and she can walk a good distance without fatigue.

January 19th, 1878.—Nearly two years after attending her, I again examined her chest. There was some hollowing under the clavicle, and the percussion sound was the slightest thing duller than on opposite side. The respiratory sounds were somewhat weaker than in right apex. She has neither cough nor spit, and her general health never was better.

Ulster Medical Society
Session 1878–1879
President Alexander Harkin

CASE II.—D. D., aged twenty-three, dark complexion, blind almost from infancy, but, notwithstanding, an accomplished musician and musical composer; naturally thin, and of nervous temperament; father and mother died of phthisis. I saw him on April 26th, 1877. He lived some distance from town. His ordinary medical attendant took ill, and his locum-tenens who visited for him pronounced his disease consumption, and gave such an unfavourable prognosis that he was not again asked to visit him—in fact, he said it was useless for him to come to see him. I learned the following history:—He had had an attack of measles two months before my visit. Immediately after his recovery he got a cold, with cough and slight expectoration; he paid no attention to it, but by degrees it became worse; his appetite failed, and he was losing flesh, and he began to have night sweats.

Then he took a pain in his right side, and he got shortness of breath. The cough, expectoration, and night sweats increased. I found him very low, and much depressed in spirits. Pulse, 130; respirations, 46 in minute; tongue red and glazed. He was much wasted, and there was a large hectic flush on each cheek. The coughing brings up his food. The expectoration is very abundant and mucopurulent. The right lung was dull on percussion anteriorly and posteriorly from apex to base. Auscultation in front gave, superficially, crepitus and deeply bronchial breathing—behind, bronchial breathing. I put him on iodide of potassium, and applied counter-irritation over the lung.

30th.—Pulse, 128; temperature, 102°; perspiration so profuse that bed-linens and night-dress have to be changed twice daily. Prescribed for perspirations, pulv. Doveri, gr. 5, at night.

May 4th.—Pulse, 124; temperature, 102°; cough very troublesome, and expectoration more profuse. Subcrepitant râles and moist clicking sounds heard over lung. Clicking sounds more numerous over the fourth rib in front, and in this region percussion gives the cracked metal sound indicative of a cavity. I now commenced applying small fly-blisters at intervals on different portions of the lung, and ordered cod-liver oil.

6th.—Feels very weak; has had a severe attack of diarrhœa for last few days.

11th.—Pulse, 120; respirations, 36; diarrhœa ceased. Bruit-de-pot-fêlé most distinct; one inch higher, and to the left of right nipple, and over a large area here, there is distinct pectoriloquy and cavernous breathing. I prescribed syr. ferr. phosph. co., and six ounces whisky daily.

14th.—Pulse, 118; night sweats appear to be controlled by the Dover's powder; chest and face to be sponged with tepid vinegar, and liniment of potassium iodide and soap to be rubbed over right lung twice a day.

20th.—Moist râles more scattered posteriorly, and healthy respiration returning; appetite improving, and

night sweats much lessened; scattered creaking sounds and moist râles in front.

27th.—Does not feel so well to-day. The cavity is filled with secretion. Prescribed a stimulating expectorant, and put him on hypophosphite of lime.

June 8th.—Pulse, 108; healthy breathing heard all over posterior part of lung; dry creaking sounds on deep inspiration. He feels much better, and he is quite lively.

26th.—The respiratory sounds are now almost normal; at the apex there are some dry creaking sounds on deep inspiration, and cavernous breathing over cavity. Percussion note is becoming as clear as on opposite side. There is considerable contraction of the side, and the head is drawn over to the right, the apex beat being midway between sternum and left nipple. He has been going about in the garden for the last few days, and he is gaining in weight. From this date his improvement continued uninterruptedly, and he was soon able to resume his usual duties. I have seen him several times since, and his health continues to be pretty good. The side is much contracted, and the breathing is weaker than in opposite lung. The cavity appears to be smaller, and higher up in the lung.

CASE III.—W. M. L., aged nine; father and mother living, but the latter suffers occasionally from hæmoptysis. I first saw him on Feb. 8rd, 1878. He had a cough during the most of the winter, but, as he showed no other symptoms of ill health, no heed was paid to it. On January 27th—exactly a week before the date of my visit—he got shiverings, headache, and general malaise, and his cough became worse. On the following day he complained of pain under right clavicle, which continued until I saw him, but he was not considered so ill as that he should be confined to the house. Pulse, 108; skin hot; respirations, 24 in minute; tongue coated with white fur. On examining the chest I found dulness over right apex, and crepitant and subcrepitant râles. Throughout both lungs there were bronchial râles (scattered). I prescribed liq. ammon. acet. and vin. antimonialis, and ordered poultices and sinapisms to be applied to the chest.

February 5th.—Pulse, 94; temperature, 99°; pain now gone. The expectoration is looser, and starchy-looking. Dulness on percussion is extending downwards.

7th.—Pulse, 102; temperature, 100.5°; percussion dulness and crepitus spreading down the lung; he now suffers from night sweats. A cracked metal sound is heard at the apex, but this is the only evidence of a cavity. I prescribed hypophosphite of lime, and counter-irritation over the lung.

10th.—Pulse, 108; temperature, 101°; dulness and crepitation have now extended almost to the base. To take cod-liver oil.

16th.—Pulse, 106; temperature, 100.5°; expectoration is now purulent; dulness and crepitation extend

over the entire lung. Put him on iodide of potassium.

21st.—Pulse, 100; temperature, 102°; physical signs remain unchanged. Put him on syr. ferr. phosph. co.

March 1st.—The expectoration is now very scanty, and his cough is very much easier. Put him on calcii hypophosph. and calumba.

8th.—The percussion note is clearer from angle of scapula downwards, and crepitus has given place to subcrepitus and moist râles.

18th.—Respiration becoming normal under the scapula, and dulness on percussion disappearing, moist râles are now heard in front, and the cracked metal sound continues at apex. From this date the lung gradually cleared up, and by the end of April—with the exception of weak respiratory sounds and slight percussion dulness—no sign of disease existed in the lung. He gained flesh rapidly, and became much fatter than he had been.

I have examined his chest lately. Percussion over right apex is now more resonant than over left, which I believe is due to emphysematous distension of the weakened air cells.

The cracked metal sound in this case was not due to a cavity. It is elicited in children by percussion over inflated air cells or bronchi, due to bronchial occlusion, with thick tenacious secretion. The chest walls of children are very resilient, and percussion, under the circumstances in question, forces the air out past or through this secretion, and thus causes a sound resembling the cracked metal.

I intended bringing forward some other cases, but as my communication is already too long, I will defer them until a future occasion.

The two first cases are typical examples of catarrhal pneumonic phthisis. The third might be classed as a case of catarrhal pneumonia, but all three had undoubtedly a catarrhal origin. During the progress of a case of catarrhal pneumonic phthisis, and as a result of the inflammation and irritation set up by the diseased products in the air cells, there is an increase of growth of the interlobular fibrous tissue of the lung. In cases that recover, this fibrous tissue contracts the lung, and indirectly the chest wall. The walls of a great many of the air cells in the part of the lung affected are so damaged by the catarrhal inflammation that they become agglutinated together on the removal of their diseased contents, while others not so much injured become distended on the subsidence of the disease. This was the result, I believe, in Case III., because the percussion note was, if anything, more resonant at the apex affected than at the sound one, although the breathing was much weaker. In Cases I. and II., I believe, there was combined with cellular agglutination an increased growth of the interlobular fibrous sheaths, because in both cases, and especially the latter, there was marked contraction of the chest wall, with weak breathing and comparative dulness on percussion. In

all there is limited expansion of the affected lung. With reference to treatment, I am inclined to place greatest reliance on a course of iodide of potassium to begin with, and followed afterwards by the phosphates or alkaline hypophosphites, with cod-liver oil internally, and moderate and repeated counter-irritation by blisters and iodine applications externally. The greatest difficulty one has to contend with in the treatment of these cases is to get patients to persevere and to rigidly adhere to the directions, because once a patient or his friends begin to regard his case as one of consumption, all remedial measures are thrown aside, except the old stereotyped cod-liver oil treatment and change of climate. I would treat all these cases in the early stages as I would any other acute disease, by confinement to bed, or, at all events, to the house.

William Aickin M.D.

Ninth Meeting March 25th 1879

Present, Dr. Aickin, Dr. Wales, Professor Dill, Workman, Dempsey, Fagan, Withers, Rea, Mckenzie, Esler, Whitla, Harkin President, Dr. Young, Speer, and many students.

Dr. Whitla exhibited a patient with a stricture of gullet of 5 years standing following sulphuric acid poisoning.

Paper:¹ The patient was nineteen years old. Five years previously she was admitted under his care into the Royal Hospital in a state of great collapse after swallowing a quantity of strong sulphuric acid. She was then about fourteen years old. The usual remedies were employed. He said that it was needless to remark that the stomach pump was not used. She made an excellent recovery, and left hospital in about three weeks. After six months she was again admitted, suffering from symptoms of obstruction of the gullet. Bougies were employed, and she left considerably relieved. He lost sight of her till about a year ago, when she presented herself in a state of great emaciation, and seemed totally unable to swallow anything, even milk was regurgitated, and there was bleeding from the seat of stricture. A No. 2 catheter refused to pass into the stomach. The stricture was close to the opening through the diaphragm. The catheter caused considerable pain and bleeding. He was at a loss for an instrument sufficiently soft to use without giving pain, and yet firm enough to make way, and he found that sea-tangle, fresh and undried, answered his purpose best; and, after some time, he was able to dilate the stricture, and keep it open whilst healing of the ulceration went on, and now he was able, as the members of the Society would see, to pass the large bougie which he held in his hand, and which was as thick as the middle finger. The patient now was able to swallow anything without pain. He brought the case forward simply to have it

¹ [Dublin Journal of Medical Science, 1879, v68, p175.]

placed upon record. Such cases were rare, and he did not remember a recorded case where so long a period as five years had elapsed with a patient living with a narrow stricture from strong corrosive poison.

Professor Dill showed a specimen of large fibroid tumour removed from the uterus. He detailed the operation and gave the history of the case.

Paper:¹ MR. PRESIDENT AND GENTLEMEN,—Had I reflected for a moment when I at first proposed to bring this case under the notice of the Society, I should have also stated that I would use the opportunity to offer a few remarks on some other cases of fibroid tumours; and, with your permission, Sir, I may do so still. I have not had sufficient time to bring this subject before you in such a way as I should like, or as its importance deserves; but I think it is possessed of sufficient intrinsic interest to make it acceptable.

The subject of the case to which I would first beg to direct your attention is that of an unmarried woman, about thirty-five years of age. On the 10th July, 1878, I was asked to see her in consultation with Dr. Wilson, of Whiteabbey. She had been complaining for seven years, and her illness was principally recognised by the fact that she suffered much from frequent attacks of menorrhagia. At the time of my visit there was a profuse discharge of blood. She suffered much from dysuria, irritation of the rectum, and irregularity of the bowels; she had lost flesh considerably, and was very anæmic. On making a vaginal examination, I discovered a large tumour which engaged nearly the whole of the pelvic brim, the base of which appeared to be embedded in the substance of the wall of the uterus, and extending from a little above the posterior lip of the os to a point very near to the fundus uteri. That part of the tumour which presented was smooth, somewhat globular, very firm, and like a child's head offering at the brim of the pelvis.

Although the patient very much desired it, yet we did not think, from the state she was then in, that we would be justified in operative interference. She was placed upon iron, ergot, sedatives, with a full diet, under which treatment the symptoms, general condition, and her strength became improved after some time. No alteration, however, appeared to take place in the tumour.

On the 18th March, 1879, I was again asked to see her with Dr. Wilson. The tumour had now appeared to have increased a little in size from the time I had first examined it; and, as the patient had become anxious about her state, and desired, if possible, that the tumour should be removed, and as we could not discover any insurmountable difficulty in the way, we consented to enter at once upon the operation for its removal. We placed her upon the left side, near the edge of the bed, or just as in the case for an ordinary confinement. As

she refused taking chloroform, I gave her a 2-grain pill of opium, which I have found useful in protracted operations either with or without chloroform. The bladder and bowels having been previously emptied, the first step in the operation was to get the tumour down and within easy reach, which was attempted by seizing hold of it by means of a vulsellum. This instrument was not found of sufficient strength or power, neither did it keep a good hold of the tumour, and had to give way to the midwifery crotchet with the shield, which answered the purpose uncommonly well, as by this instrument the mass of tumour, which yielded slowly but surely, was safely brought down and outside the vulva. The base, or its attachment to the uterus, which was broad, was then transfixed with a large needle, armed with a double ligature of whipcord. The ligature, being brought half-way through, was divided and tied firmly on each side. Although the operation was a tedious one—lasting altogether more than two hours—yet the patient did not appear to suffer much when it was over, and she slept well the first night, which I ascribe to the timely use of the opiate. The ligatures came away at the usual time. Since that she has menstruated naturally, and she is now—two months since the operation—going about her ordinary business, strong and well. The tumour weighed 9 ozs. 7½ drs. I have given small portions of the tumour which I now exhibit to Dr. Workman, who is prepared to give you his microscopic observations of it. I may conclude this case by stating that, from the first, I was satisfied of it being a fibrous tumour and not at all malignant.

The second case is one which a few words will dispose of. The patient, after being married for five years without any issue, got into bad health, with occasional attacks of menorrhagia. A very large pelvic tumour had existed for a long time. I then saw her with Dr. D. Johnston, when the tumour was so large that it could not pass the brim of the pelvis. We concluded, from its size and from other reasons, that it was not a case for operative interference, and prescribed iron, ergot, &c. We saw her again, in consultation, some short time afterwards, when we thought the tumour had somewhat diminished in size. We prescribed some local application and bromide of potassium inwardly. She was sent to the country, and, again, to the seaside, for change of air. I saw her a third time, at the end of a year, when I found that the tumour had completely disappeared. I could get no exact history as to how it decayed or disappeared, but that she had become quite well and free from the tumour was without doubt.

The third case is one very similar to the second—a patient of about forty years of age. She had been the subject of many attacks of excessive menorrhagia. I saw her on one of those occasions with Dr. M'Crea, when we prescribed for her, and suggested that at some future time she might be fit to undergo an operation. I saw her, back and forward, for some weeks. She was then

¹ [Dublin Journal of Medical Science, 1879, v67, p542.]

sent to the country, and when she returned, at the end of twelve months, the tumour was quite gone, and she appeared to be in tolerably good health.

The fourth case I saw with Dr. H. M. Johnston, who sought my assistance in a complication of labour by a large fibrous tumour. I examined and found a very large, hard tumour of the uterus, low and to the left side. The head of the child could neither be induced in any way to pass the tumour nor could the tumour be induced to pass up beyond the head. After many fruitless efforts to relieve the woman, and being satisfied that now the child was dead, we resolved on reducing its head, and we experienced no difficulty in extracting it. The tumour was such as to invite immediate removal, which was done, and the mother made a good recovery.

The older members of the Society will remember (as I well do) a very interesting case introduced here by the late Dr. Johnston, which occurred in his practice in the Union Workhouse. It was that of a poor woman who took ill in labour in that institution. Dr. Johnston had watched the case with interest for some time. The os was dilating, but the head was making little or no progress. He left her for a short time, and during his absence the pains, which had been strong, suddenly ceased, and, before he could get back to her, the woman was dead. A post mortem examination was made, when a large rupture in the body of the uterus was discovered. A fibrous tumour the size of a cricket ball was found growing at the fundus uteri, towards the right side, and it was also firmly attached to the lower edge of the liver. Evidently the tumour had risen with the increasing size of the pregnant uterus, and in the end it had been pressed against the liver, to which it had become adherent, thereby so bridling the uterus as to prevent it from contracting, descending, and expelling the fetus. The result was rupture of the uterus, and, consequently, the death of the mother and the child. Both might have been saved if the woman's condition could have been diagnosed or clearly anticipated.

My sixth and last case was that of a lady whom I attended for a long time. At first she suffered from severe pain in the lower part of the abdomen and towards the left side. A tumour could soon be discovered in the same region. I was always satisfied, from its position, shape, and size, that it was attached to the uterus, and that it was of a fibroid character. This lady consulted many surgeons and physicians, both here and elsewhere, but it was not satisfactorily diagnosed by any of them, nor the exact nature of the enlargement stated. At the end of more than three years of suffering and doubts regarding the result of the disease, suddenly she was seized with very acute pain and torture, which after a few days became somewhat relieved. I could now feel the tumour freer and rather movable in the abdominal cavity. After some weeks I thought I could feel it becoming fixed, and in the end adhering to the inner and

peritoneal surface of the abdominal walls. The abdominal parietes became inflamed at their point of attachment, and after being poulticed for a time, an abscess formed, gave way, and discharged for a long time. The lady eventually recovered, and she now enjoys good health.

The fifth and sixth cases are full of interest and valuable instruction, because of their varied condition and the somewhat peculiar termination of each. They also verify the fact that such tumours are not confined to the mucous surface, but that they also form upon the peritoneal side of the uterus, and that fibroids may form upon or take as their origin any point of uterine fibre.

These cases may, I trust, though imperfectly stated, be of some interest, and form a small contribution to your "Transactions." The first is of interest in the fact of the woman having been so long ill and in making such a complete recovery after the operation. The second and third cases are possessed of interest from having made—shall I call it?—spontaneous recoveries, by involution, atrophy, and decay. The fourth was one of unusual interest, complicated as it was with pregnancy and labour, and, with all, the woman having made a satisfactory recovery.

Discussion.¹ DR. AIKEN said that Professor Dill had spoken of two cases where the tumours had descended. He explained this as owing to the contraction of the os, and he thought that once the tumour got through the os the removal was easy. He explained how the melting away was accomplished. He believed it was atrophy by the force of uterine pressure. He detailed a case under Dr. Johnston where death occurred from hæmorrhage from a fibroid after birth. He detailed a case of his own where the pressure of the uterus caused the absorption of a large mural fibroid.

DR. FAGAN thought if Professor Dill had used other means than the ligature he would have had less trouble—there would have been less danger of hæmorrhage and pyæmia. He would have used the *écraseur*. He thought that where hæmorrhage declared itself, and the cause was known, operation should be at once decided upon.

DR. ESLER thought that the *écraseur* or thermo-cautery would have been better than ligature. He thought that Dr. Whitla's case of stricture of the gullet was of great interest. He remembered the then child in hospital, and the prognosis was very grave; the most sanguine gave two years as the limit.

DR. HARKIN.—The subject of uterine fibroid tumours which has been presented to us by Dr. Dill must have interest for every one charged with the treatment of the diseases of women. The case seems to have been managed for so far very successfully, and the tumour

¹ [Dublin Journal of Medical Science, 1879, v68, p173.]

removed appears a typical one of that troublesome class. In my own experience I have had some remarkable examples, but shall only refer to two—the first and the latest. I find in my notes of the first, that I was called on February 10, 1842, to visit M. D., a domestic servant, aged fifty, mother of three children, but a widow of thirteen years. She informed me that six years before at the cessation of the menstrual period her health became impaired, two years subsequently she began to suffer from a sanguineous discharge from the vagina, at times taking the character of pure blood, the latter was checked by cold applications and astringent injections; soon afterwards she was attacked by severe pains in the hypogastric region, from which she slowly recovered.

On visiting her at 11 p.m., I found her lying on her back, her legs widely extended, and a large firm globular tumour protruding from the vagina; the bedding was saturated with blood, pulse feeble, and extremities cold. Great difficulty was experienced in making the necessary examination, the os externum being completely plugged by the tumour. After a consultation with Dr. Burden, it was determined to remove the tumour, but on grasping it firmly previous to passing a ligature round its pedicle, the latter gave way, and the whole body of the tumour separated from its attachment without any further hæmorrhage; the patient made a good recovery. On cutting into the substance of the tumour, it appeared fibro-cartilaginous in structure, a layer of a circular form and pearly colour—it weighed 1 lb. oz., measured 11½ inches in smaller, and 15 inches in greater circumference. The tumour was deposited by the late Dr. Burden in the Museum of Queen's College, Belfast, where it may still be seen in a good state of preservation.

The other case was also one of fibroid attached to the os uteri, about the size of a pullet's egg, and occurred in a woman of full habit of body who had not borne any children. I was brought to see her on account of profuse hæmorrhage at the monthly period. On examination the cause was detected and two attempts were made in conjunction with the late Dr. Pirrie to remove it; we only partially succeeded, the patient refusing to submit to any further surgical treatment. The hæmorrhage continuing profuse, after the failure of other remedies, I had recourse to the hypodermic injection of the liquid extract of ergot, with the satisfactory result that there has not been any return of the hæmorrhage after an interval of more than two years, and the patient's health seems quite established.

DR. DILL (in replying to Dr. Aiken's statements about the natural cure from pressure of the uterus) said this cure was not by atrophy but by enucleation and consequent starvation; they were very poorly nourished. It was not the pure fibrous tumours which melted away, but the fibro-cystic, and he explained the supposed process. As regarded the preference to the *écraseur*, he

never fell out with old friends. His reason for using the ligature was the very large size of the base of the tumour. He did not believe with Dr. Fagan that the use of the *écraseur* left no foreign body behind it; the bruised part, or stump, left by it was the worst form of foreign body possible to conceive. He quoted the authority of Simpson and others in support of this.

Dr. Workman, Pathological Secretary, showed microscopic specimens of the above tumour.

In the absence of Dr. Smith, a cancerous stomach was exhibited.

Dr. Fagan showed a specimen of loose cartilage from the knee joint. Also the head of the humerus removed in excision.

Dr. Young showed for Dr. O'Neill a specimen of stenosis of the aorta.

Alexander Harkin, President

Tenth Meeting Wednesday 23rd April 1879

President Dr. Harkin, Professor Dill, present Dr. John Moore, Dr. Aickin, Dr. J. W. Browne, Dr. D. Johnston, Dr. O'Neill, Dr. Esler, William Whitla.

Dr. Dill read a paper upon "Some general considerations on the forceps and a few remarks on the use of this instrument in modern obstetric practice".

Paper:¹ It is altogether unnecessary for me to attempt giving an account of the almost countless varieties of midwifery forceps which have been designed and furnished to the profession since the days of the Chamberlens, now over a period of more than two hundred years. I may be permitted, however, to say that the author of each variety believed there was a superiority and some great advantage in his own design over any other which had appeared before. For a long time, and until within the last forty years, the short forceps was, I may say, the only instrument in common use here as elsewhere. Now, however, it has almost altogether given place to the long forceps; and while I have always given the preference to Simpson's, I believe that Dr. Robert Barnes' long forceps is now received with more general favour. And this is even the case at present in the Dublin Obstetric School, where formerly almost every leading accoucheur had an instrument designed by himself and known by his name.

For so far we, in Belfast, have been satisfied to accept of, and make a choice from among those which have been furnished to us, and which have been recommended by other schools. Still Belfast has not been behind in the increasing but legitimate use of this most necessary and valuable instrument. For I remember well, when it was not much used here, that the late Dr. M'Clurcan, of Belfast, got into high repute in the town and neighbourhood, because of his very extensive and successful use of the midwifery forceps. Dr. M'Clurcan

¹ [Dublin Journal of Medical Science, 1879, v67, p486.]

practised from an early part in the present century until near the middle of it, and from his day to the present time it has been growing in greater and still greater favour.

One incident, and a remarkable one to us now, will strongly mark the difference between the past and the present practice. The late Dr. Samuel Thomson, of Belfast, one of the most eminent physicians of his day, in the north of Ireland, and who held a very large midwifery practice, told me, shortly before his death, that he had never used the forceps in his practice, which had then extended over the long period of forty-five years, and he died in the year 1850. This is a striking contrast to the junior practitioner of the present day, of whom I am safe in saying that he will not be in general practice one year without using the forceps more than a dozen times.

I presume I shall not, with my present audience, be considered as at all overstating the case if I assume that the midwifery forceps, its application and its uses, should be treated as amongst the most important and interesting questions for discussion in the whole range of obstetric practice, involving as it may do, the life or the death of both the mother and the child. Because, if the judicious and skilful use of this instrument be exercised, then safety to the mother and child must be the result. But if, on the contrary, the operation be proceeded with either untimely or by a clumsy and unskilful hand, then is it not more than likely that the consequences shall prove to be most disastrous? We know that in the beginning of and till far on in the present century, delay was practised to a dangerous extent, whilst latterly there has been more than the tendency abroad to an early, if not to the too free, use of the forceps, and especially in the Dublin School of Midwifery, where its introduction has been recently advocated by at least one leading accoucheur before even the os uteri has become fully dilated. I am not at present at all disposed to enter upon a defence of either the one extreme or the other, for in the one case injuries may be allowed to occur from delay and in being too tardy in entering upon the operation, whilst the other may unnecessarily lead to accidents by rashly acting too early. That we may avoid both of these dangerous errors—and which I shall take leave to designate as the Scylla and the Charybdis of obstetric surgery—I am rather inclined to advise here the adoption of a motto borrowed from Ovid's "Metamorphoses"—*Medio tutissimus ibis*.

In the table of statistics of delivery by the forceps, according to Churchill, we find that among British practitioners the forceps was used about once in 450 cases; in France, once in 140 cases; and in Germany, once in 107 cases. And now, when we consider the very frequent use of this instrument in modern practice, we must come to the conclusion, when the time arrives for making a return of the statistics of such cases again, it will be found that they far exceed the largest of the fig-

ures which we have quoted above. It may therefore be accepted as an admitted fact that this instrument is much more frequently used in the present day than it formerly was. And, notwithstanding all that has been stated, if we except those cases in which the forceps has been used before the os uteri was fully dilated, I feel strong in the opinion that at no previous time within the history of obstetric surgery was it ever so successfully used as it is just now.

Amongst the most striking returns on this point are those contributed by Dr. Hamilton, of Falkirk, and which are worthy of some attention. Dr. Hamilton uses the forceps about once in every seventh or eighth case, and he has thus delivered 731 successive children without a single still-birth, which would form a remarkable page in obstetric history, were he able at the same time to record an equal number of successful results on the part of the mother; but, unfortunately, he makes no return, as far as I can discover, on this branch of his subject.

In further discussing this question I would beg to remind you that just as ergot is forbidden during the first stage of labour, so also should we forego the use of the forceps until at least we have reached the second stage of labour.

Dr. Leishman, in discussing this question, gives it as his opinion "that before the application of the forceps it is absolutely an essential condition there should be complete dilatation of the os uteri." And again he says, "An essential condition is, according to all authorities, that complete dilatation of the os should first exist before the introduction of the forceps."

Dr. Playfair has expressed the opinion, in his work on the "Science and Practice of Midwifery," "that the use of the instrument before the os uteri is completely expanded is a very serious matter." And Cazeaux, a very eminent French authority, while discussing this subject, tells us "that before we apply the forceps we should wait, in ordinary cases, till the membranes are ruptured and the os uteri fully dilated."

I could multiply such quotations almost ad infinitum, but I do not wish, by doing so, to tax your patience further upon this point, and the more so as I believe I have already proved to your entire satisfaction the correctness of my position—which is, that in ordinary cases of labour the forceps should not be used before the os uteri is fully dilated. But if more proof were needed, I have only, I hope, to appeal to your own experiences for a complete confirmation of the correctness of my statement.

I find, however, in the number of The Dublin Journal of Medical Science for last January, a "Report" presented to the Dublin Obstetrical Society by Dr. George Johnston, ex-Master of the Rotunda Lying-in Hospital, in which he advocates "delivery by the forceps before the os uteri is fully dilated;" and he has satisfied himself that this practice is not only safe and justifi-

able, but also a great preservative of the lives of both mothers and children. Now, if we were able to satisfy ourselves, as he has done, then it would become a duty with us not only to read and discuss, but also to mark, learn, and practise, according to the rules laid down for our instruction in the "Report" to which reference has been made. But the discussion which follows upon that "Report" throws very important light, and affords some valuable information on the subject; and I think it but due to Dr. G. H. Kidd in particular to say here that in my opinion his statement is a very able, clear, and conclusive answer to Dr. Johnston's important "Report."

Dr. Kidd furnishes us with the statistics of what he is pleased to call "the old school," and he compares them with the information which he gleans from "the new mode of practice," as contained in the "Report," thereby eliciting the fact that the mortality which is found to have existed in the former is but 1.21 per cent., whilst in the latter there did occur a percentage of 2.27, being about double the number of deaths in Dr. Johnston's practice when compared with the practice of the masters who had gone before him in the Rotunda Lying-in Hospital. But when we come to that part of the "Report" which relates more especially to those cases in which the forceps had been used before the os uteri was fully dilated, we find that the result is still worse; for of the 164 cases delivered with the forceps before the os uteri was dilated, and in which cases there cannot be discovered anything beyond the fact that they were ordinary cases of tedious labour, six deaths are recorded, being at the rate of 3.6 per cent., whilst in tables of tedious labour compiled by Churchill the mother's mortality is put down at nil. I might accumulate comparisons of this kind further, but I think I have demonstrated the fact that delivery with the forceps before the os uteri is fully dilated is unsafe, and, consequently, should be considered as unsound in practice.

Under such circumstances as these, and with the facts and the figures before us, is it necessary that I should formally ask the question are we to adopt the teaching, or, as it has been termed, the "new mode of practice," as recommended in Dr. Johnston's "Report;" or shall we adhere to, and pursue, the more moderate means of delivery? For my own part I have no hesitation in stating that I see no reason why I should give up the latter course, as it has been proved to be the safe one; whilst the former I consider not only a dangerous course, but nothing short of an entrance upon a downward if not fatal career—a career to which we might not be far beyond the mark by applying a not inappropriate expression from Virgil's *Æneid*—*Facilis descensus Avernus*.

When I first heard of this "new mode of practice" I was almost tempted to apply to it, in a modified form, the Russian expression, which was used in regard to the light cavalry charge of "the Six Hundred"—that it was une charge magnifique, mais une charge de fous. So of

the "new practice;" it was une opération magnifique mais une opération de fous.

Although I have spoken thus strongly, perhaps too severely, it is only in regard to the use that has been made of the forceps before the os was dilated. At the same time I might be misunderstood if I stopped here without saying that there are certain cases to which the foregoing statements do not apply—such as in the case of a somewhat narrowed pelvis, and in which the os uteri does not become fully dilated because of the forces not being brought to bear upon, or directed towards, its axis, so that in this case, and from a few other causes that demand its use, the period of labour for applying the forceps must necessarily vary.

And now, Mr. President, I have only to say in conclusion (after apologising for trespassing upon your patience with such an imperfect paper) that time would appear in this, as we know it has become in other matters, the absorbing interest of the age. And I think I hear it asked why should we be behind in the race? From my own experience I am much inclined to counsel some prudence and a little more delay. For although we may, by assisting to bring about a hasty termination to a case, win the applause of the moment, we may rest assured that the calm and thoughtful physician, and the skilled and patient accoucheur, will in the long run have a more just and a more abiding reward.

Discussion.¹ AT the conclusion of Professor Dill's Paper he exhibited an interesting diagram of the different sizes of the os uteri.

DR. D. JOHNSTON thought it a question where each should have a fixed principle in his mind about the use of the instrument. He had applied the forceps at every stage. He had no hesitation in saying that in suitable cases the instrument should be applied early, for in the class of cases where the long forceps were indicated seldom does the os fully dilate (the obstruction prevents it), and if we waited for full dilatation we would wait till too late. He laid great stress upon the character of the os as a guide. He had not seen a fistula, and he had delivered 4,000 or 5,000 women, and used the instrument once in every ten cases. He thanked Dr. Dill warmly for his paper.

DR. ESLER commented upon the change in practice in Dublin. He showed the way in which the statistics quoted by Dr. Dill, in reference to Dr. Johnston, might be fallacious. The numbers being too limited, he would side with Dr. Johnston.

DR. AIKEN thought that the character of the os was of great importance. He advocated the "gouging" process, especially in rigid cases; he had practised it scores of times successfully. He found it hasten labour very much. He would not use the long forceps in rigid os, on any account, without a previous dilatation by the fingers. He commented upon the relative merits of

¹ [Dublin Journal of Medical Science, 1879, v68, p170.]

Barnes' and Simpson's instruments, and believed that Simpson's had the advantage. He explained a method of wrapping the handle of the instruments with a handkerchief by which he can alter slightly the axis of the blades.

DR. MOORE thought the question narrowed itself into those cases of unobstructed but tedious labours. Twenty-four hours was the limit to healthy labour; if past this there must be an important cause at work. There was no danger whatever in delay in the first stage of labour; he held this to be of very great importance at the start. With unbroken membranes and undilated os, wait, most decidedly. He was sorry Dr. Dill did not bring prominently forward the character of the os. He detailed instances where a medical man was imperatively called upon to deliver without waiting for full dilatation. If the os is rigid, two things are given us to choose between: either the os will tear, or uterus, child, and all will come with you. With these conditions—a rigid os and unruptured membranes—he would say wait. With these exceptions he would agree with Dr. Dill. He thought the choice of the instrument was more a matter of the attendant's habit. We got great skill with the use of any form after a time. He cautioned the junior members against the habit of tying the handles, which should be allowed to dilate and contract with each pain. He detailed cases where great suffering and damage was caused by the delay in their application.

Dr. WHITLA would not express any opinion upon the advisability of using the instrument in cases of undilated os, as his own experience was not sufficient to lead him to a conclusion; but he was sorry Dr. Dill, in his able paper, did not refer to a method which was now sweepingly advocated in England—i.e., the clandestine use of the instruments, which he thought was a disgrace to the profession.

DR. HARKIN.—I think that the Society should be very grateful to Dr. Dill for the manner in which he has introduced the all-important subject of the use of the forceps in general, and specially in reference to its place in modern obstetric practice. Just now the minds of medical practitioners are agitated by the advocacy of the use of the forceps in the first stage of labour in strange contrast to the timid teaching of the authorities of forty or fifty years ago, and to the practice approved of by the present race of obstetricians. It is then most fitting that Dr. Dill, both as teacher and practitioner, should give us the result of his matured observation, and bear his testimony on one or other side of the debated question. In my experience there has been a well marked ebb and flow upon the subject of instrumental assistance in prolonged or difficult labour. In the first decade of my professional career the use of the forceps was much discouraged, and its application surrounded with such guards and exceptions that it required a certain amount of courage even to mention the subject. Denman's dictum was always acted on, and

it was considered a necessary preliminary that "the ear of the child should be distinctly felt." The short forceps was then perhaps tentatively applied, while at present that instrument is practically discarded, and the long forceps preferred in every case, and by some authorities applied, as a rule, in tedious cases, even before the os uteri is dilated, and the head still above the brim. The tide is now evidently on the flow, and if we have not prudence at the helm we may launch our bark into trouble and discomfiture.

It is quite true that the late Dr. Thompson, in his time the father of the profession in Belfast, frequently stated that in his lengthened experience he had never once had recourse to the forceps; but Dr. Dill must have forgotten to mention that instead of the double blade he had always used the vectis—and this too was my custom in the earlier years of my professional life when engaged in a case of difficult and prolonged labour. I soon, however, learned the superior advantages of the forceps and now only have recourse to the lever in breech presentations when the head is detained in the outlet of the pelvis.

In this predicament the single blade has many advantages over the double-bladed forceps, not alone from its firmer and more unyielding structure, but from the greater curvature of its broader end. The attempt would be idle, from an array of statistics, to formulate a law for our guidance in the use of the forceps. Some men apply them frequently, others very seldom, and each may triumphantly point to results as satisfactory as the other. Each case must eventually be judged upon its own merits; and while, as I have said, an equal degree of success may be claimed by either class when the safety of the mother alone is accounted for, my opinion is that the advocate of more frequent instrumental aid may justly claim greater success in the saving of infantile life, the great end and object of labour, or, as it is properly styled, childbirth. I would then try to impress upon the younger practitioners in midwifery the desirability of attaining early in life a facility in the use of the forceps, for with this acquirement, accompanied with a proper amount of self-reliance, many a parturient woman may be saved from hours of thriftless labour and pain, and the child not seldom from the dreadful alternative of craniotomy. It is awful to contemplate how often this lethal weapon is preferred even by tyros to the bloodless forceps. In my lengthened experience I have known of too many such; and I may, in passing, refer to a statement made at a branch meeting of the British Medical Association in England, when a member, during a discussion on the merits of the forceps, stated unreservedly that while acting as assistant for a number of years to a doctor in a midland county in Ireland, he had never once seen the forceps used in a difficult case, as the perforator was the only instrument chosen to effect delivery. As to the question of applying the long forceps as a rule in

Ulster Medical Society
Session 1878–1879
President Alexander Harkin

the first stage of labour, with the head above the brim and the os undilated, I should hold with Dr. Dill, and only interfere in this heroic manner when an insuperable disproportion had arisen between the expulsion power of the mother and the resistance offered by the maternal structures to a head of large size, or in a mal-position.

In cases of difficulty and danger of this sort I have, both alone and in consultation, applied the long forceps in the first stage, and with a happy result both to mother and child, after the perforator had been proposed as the only alternative; but I should always do so with reluctance, and as the safest mode of escape from a painful and dangerous position.

DR. DILL did not enter into the subject with the view of entering upon all the cases where the forceps were applicable, but mainly with the view of testing this new practice. In reference to the figures quoted by him he maintained the fairness of contrasting the two classes of statistics.

He referred to the fact that the head was too often hurried down before the outlet was ready for it, and rupture was sure to follow. No one was more willing to shorten labour than he was, provided the second stage was entered. He would wish them to understand that he excepted the class of case where you would have no dilatation of the os from obstruction high up. He thought the compression should be intermittent. He explained that the sudden dilatation of the os by the head might be brought to a close, and the os might contract round the neck and be a barrier to labour.

Alexander Harkin, President

Eleventh Meeting Tuesday 12th May 1879

Present, Dr. Harkin President in the chair, Dr. John Moore, Professor Dill, Dr. Wales, Dr. Dempsey, Dr. Withers, Mr. Fagan, Dr. Esler, Dr. Workman, Dr. Wadsworth, Dr. Clarke, and a number of students.

Mr. Fagan exhibited an enchondroma he had removed from the shoulder of a patient in Royal Hospital.

Dr. Gilbert-Kirker (visitor) read a paper on his experience in surgery in the Russo-Turkish war.

Annual Meeting November 11 1879

Present, Dr. Harkin President, Dr. Wales, Dr. J. W. Browne, Dr. John Moore, Clements, Core, McConnell, Dempsey, Withers, Workman, Mckenzie, Whitla Honorary Secretary.

Minutes of former meeting having been read, the Secretary read the report of Council and also the report of Honorary Treasurer (who was absent) which showed a balance of £56 in favour of the Library.

Dr. Core reported upon the condition of the Library.

The three reports were then passed.

On the motion of Dr. Whitla seconded by Dr. Wales Professor Dill was unanimously elected President for the ensuing year.

Dr. Whitla was unanimously re-elected Honorary Secretary.

Dr. Esler's resignation was read by the Honorary Secretary but it was the unanimous wish of the Society that he remain in office.

Dr. Core was re-elected Librarian and Dr. Clarke assistant Librarian.

Dr. Workman was re-elected Pathological Secretary.

The following gentlemen (votes) were elected Council:

Dr. Wales (12), Dr. Moore (10), Dr. Dempsey (10), Dr. McConnel (8), Dr. Clements (8), Dr. McKeown (7).

Dr. Moore proposed the usual vote of thanks to the office bearers.

Thursday November 27th was fixed for Annual Dinner.

The Honorary Secretary asked for instructions regarding the gentleman mentioned in the Treasurer's report whether he should notify him to attend meetings etc. and it was resolved as he was not a member of the Society that no notice be taken of him.

R. F. Dill, President

Ulster Medical Society
Session 1879–1880
President Robert Foster Dill

ULSTER MEDICAL SOCIETY

SESSION 1879–80

The First Meeting of the Session 1879–80 November 2nd

Present, Professor Dill M.D. President, Dr. Harkin Ex-President and Dr. J. W. Browne Vice-President, Professor Cuming, Drs. Dempsey, Clements, McKee, Withers, O'Neill, Fagan, Wales, John Moore, McConnell, Workman, Esler, Kevin, Wadsworth, Whitla Honorary Secretary.

Drs. Kevin and Henry Burden were elected members of the Society.

The President delivered his inaugural address.

Paper:¹ GENTLEMEN, We have come here to-night for the purpose of inaugurating another session of the Ulster Medical Society, and I gladly avail myself of this, my first, opportunity to offer my sincere thanks to the Council of the Society for having selected and put forward my name, and to the members, who have done me the honour of electing me—shall I say unanimously electing me—President for the ensuing year.

Then, to be thus called upon by my brethren to fill the presidential chair is, I assure you, to me a source of much gratification and—shall I add—justifiable pride. For when, in the course of a long professional life, after many years spent in very active public and private work, still filling different important appointments, one finds the good opinion of his brethren undiminished, and their voices raised to place him in this elevated position among them, he would be either less or more than human if he did not feel pride in accepting this distinguished mark of approval at their hands.

I have had the honour of being a member of this Society for many years, and longer than many here could remember; and if I did not assist at the birth, I certainly did take part in the operation for its resuscitation. I have watched with interest its development, and I have witnessed its fortunes under many circumstances and at different conjunctures, and I cannot conceal from myself that I never met my friends, the members of the Ulster Medical Society, under circumstances more difficult, more embarrassing, or more trying, than I do on the present occasion.

There may have been a time when I might have been induced to accept of this office with less reluctance—indeed I shall say with more readiness than I do now—but that may have been because I was not then so keenly alive to, or sensible of, the great responsibilities with which it is associated as I am at present.

But why need I dwell on such matters, as formerly no one thought of me for the appointment but myself,

whilst latterly every one thought of me for it but myself. And if this be so, then I can with the more confidence cast myself implicitly upon the kind indulgence of the members, knowing that they will be disposed to throw their friendly mantle over the many deficiencies and numerous shortcomings which must appear with me, from time to time, during my period of office. Indeed at my time of life I should have been seeking rest, in place of taking upon me more work. But loyalty to my profession and respect for friends forbid the idea of rest, or of not obeying their call.

And now, gentlemen, when I look back over the years that have passed between the period I entered the Society and the present, I can—shall I say it—unfortunately see as much to excite feelings of sadness as I can of an opposite character. But why should we look for an exception here of an unalloyed pleasure when we so often see that—

Even mirth is gilded with sadness
Time—inexorable Time—has been busy, sending his swift shafts and plying his sharp and fatal scythe among the members; and I have seen one and another and another cut down, and fall before the fell destroyer. M'Donnell, Thompson, Saunders, Malcolm, Reade, Stephenson, Stewart, Burden, Johnston, besides many other distinguished members I could name, have died since I joined this Society.—No; they still live, and are enthroned in many hearts—they are embalmed in many a memory! But when I look up and around upon this numerous meeting, and when I see these well-recruited ranks again filled by men who have already proved themselves possessed of so much intelligence, ability, and discipline for their work, and when I hear of such favourable accounts from your able and unwearied secretary, Dr. Whitla, as well as when I am told of the very satisfactory results arising from the indefatigable exertions of your worthy treasurer, Dr. Esler, I think I am more than justified in giving expression to the opinion that there is much ground for encouragement, much to inspire confidence, and enough to bespeak a prosperous future for this much-esteemed and very useful Society.

And although, as we have seen, one generation cometh and another generation goeth, yet methinks I hear the whispered sentiment, as it floats upon the breeze—

All men think all men mortal but themselves.”

But men may come and men may go,
But I stay on for ever.

And now, gentlemen, at the risk of wearying your patience, I venture to occupy your attention a little longer with a few observations regarding the nature, the qualifications, and the responsibilities of the medical profession. I hold what I feel persuaded no one, at least here, will deny—viz., that to perform the important functions of the medical profession a medical man

¹ [Dublin Journal of Medical Science, 1880, v69, p67.]

must be possessed of a higher and more varied order of talents, as well as of more extensive learning and acquirements, than are considered necessary for the other professions.

Take, for instance, divinity, law, and physic, which are always spoken of as the three learned professions, and of these there is not one that requires a knowledge of such a wide range of scientific subjects as is demanded by medicine, surgery, and obstetrics.

The student of theology, although admittedly occupied with the highest subject that can engage the attention of man, still is occupied with but a single subject; and law presents to its votaries little or no variety or interest, occupied as they are with the perusal of old, dusty, musty parchments, made venerable, if not by years, by the depth, of dust which gives them weight, and almost seals them to their shelves. And so "law is law."

But what shall I say for medicine. The number of sciences required here are all but endless, and the grandeur of the object which the physician has set before him when he enters on his work is indeed unbounded. He must be intimately acquainted with the body as one great and wonderful machine—with its two hundred and fifty bones; with its four hundred and sixty muscles; with its myriads of vessels and nerves, which are quite beyond my arithmetical powers for calculation; with its heart-pump constantly sending the vital fluid through ten thousand channels, at the rate of more than one hundred thousand strokes a day, for seventy years or more. He must also be acquainted with the way in which these materials are prepared, with the manner in which they find their way into the system, with the mode in which they are purified, and, when they become effete or worn out, with the way in which they are eliminated and again renewed. He must, then, be acquainted with the brain and nervous system, from and by which every part is supplied, and out of which supply come sensation and motion—and, at the same time, do not these threads of nerves convey from head to hand the telegraphic commands of the will?

When this magnificent machine is in active operation we can easily see and recognise results, but we cannot comprehend that most wonderful and mysterious association which exists between it and what is called life, or that still more mysterious association which is found to exist between mind and matter.

In this wonderful structure or contrivance we discover a furnace, combustion, a chemical laboratory, a galvanic battery, a force-pump; and all mechanical appliances and powers may be found at work in this one system, and which would require more than a knowledge of anatomy to give one even the most superficial, the faintest, idea or insight into its workings. To a knowledge of anatomy we must add physiology, histology, pathology, and chemistry. When this great work is completed we must then enter upon a new series of sci-

ences—viz., *materia medica*, botany, zoology, medicine, surgery, obstetrics, and other collateral sciences. And, after all, we are but on the threshold, the border-land, of the field which must be occupied and cultivated by the high-bred, educated, and practical physician.

It were unnecessary before this Society to urge the matter further, or, in establishing my position, to go more minutely into detail; but as students are admitted (and very properly) to our meetings, and as they are to fill our places hereafter and when we are gone, I trust to the kind consideration of the members if, for their sakes, I am drifting into other lines than those which should be kept in an address to a learned Society. Will you, then, allow me to proceed by endeavouring to prove that there are other qualities required by the medical man besides the sciences and the learning of which we have been speaking. By the late Dr. Stokes it was considered necessary (and everything this eminent Dublin physician uttered should be remembered) that the youth when entering upon his professional studies should, in the first place, have a medically constituted mind, or he should exhibit an aptitude for medicine, or, as I believe he termed it, be in possession of the "*mens medica*," before he could expect to attain to any degree of distinction, or even the smallest amount of success in the profession. Indeed, he considered this as a *sine quâ non* for success. Under all the circumstances I would be disposed to say that the case stands thus:—The physician must first have an aptitude for medicine, he must next have a knowledge of the sciences, he must also have not only a large and overflowing measure of the *suaviter in modo*, but he must have, in addition, a proportionate amount of the *fortiter in re*. These qualities harmoniously blended are sure to lead to fortune. Without them the physician must soon discover, before he has travelled far on his journey, that "there is a lion in his path."

That much may be done by training, culture, or by art and education, to overcome natural deficiencies or obstacles to professional success, no one will deny; but that there are marked predispositions in individuals to certain pursuits, which it is always well to seize hold of and cultivate, is a proposition which, I think, most persons must accept. There are one or two very appropriate stories which, although you may have heard before, I think may be happily used here to illustrate the point under consideration. Human life has been compared to a broad table pierced with numerous holes, each of which has a pin made exactly to fit it, but which pins, if stuck into these holes in haste, at random, or without selection, must lead to very awkward errors, and, sometimes, disastrous consequences. And in the same way we may speak of men. If the round man be taken and forced into the three-cornered hole, and the many-sided or square man be driven into the round hole, the misfits must lead to serious blunders and most grievous mistakes. The other is that one which has been recorded

Ulster Medical Society
Session 1879–1880
President Robert Foster Dill

of Cecco d'Asceli and of Danté, while discussing the subject of natural and acquired genius, and which I shall here advance to further illustrate the matter in hand. Cecco d'Asceli held that nature was more powerful than art, while Danté asserted the contrary. To prove this principle, Danté, the great Italian bard, introduced his cat, which by practice he had taught to hold a candle in its paw while he supped, or sung, or read. Cecco d'Asceli, who before this had expressed a desire to witness the experiment, came prepared for the occasion. While Danté's cat was performing its part, Cecco suddenly lifted the lid of a pot which he had cunningly filled with mice. The creature of art instantly showed the weakness of a talent which had been purely acquired, and, dropping the candle, flew on the mice with its instinctive propensity. Danté was himself much disappointed, and was obliged to admit that nature and the natural gifts or faculties were more to be depended upon or trusted than art. I could, if it were necessary, give other facts by way of illustration, but I think I have said enough to prove the necessity for—first, the natural gifts and dispositions of the mind should be bent on an object, and, second, that when these faculties are properly cultivated that object is more easily reached. To my mind there is no profession more imperiously demands a predisposition than medicine, and this, combined with culture and natural courage, must as a consequence, as I have already sketched, lead to fortune. Moreover, if, in addition to all these great and necessary qualities, the physician be possessed of that identification—that sympathy of feeling with his patient's interests—he must command a confidence, and wake up a responsive echo in the soul which no material means can ever accomplish or make attractive. How could it be otherwise, for what has been spoken of is natural genius—it is a heaven-born gift which, while it may be fostered and cultivated, can never be communicated? This sympathy and identification of feeling would seem to possess a power and penetrate into regions where art, or that cold and icy philosophy of the age, are quite inaccessible.

I would, then, respectfully but confidently submit, that if this complicated machine—this wonderful mechanism—is to be preserved, this remarkable casket, containing as it does such a precious jewel, is to be renewed, I should rather think it would be safer in the hands of him who can with perfect knowledge, disposition, and culture correctly estimate the value of the treasure, than be placed in his hands who is imbued with the chilling philosophy of the times, and who in the end would consign the whole to the maelstrom-whirlpool of destruction, or, as a modern scientist expresses it, “in the end but melts away into the infinite azure of the past.”

But I have to congratulate the Society that its members have no sympathy with such doctrines and sentiments as these. On the contrary, does it not belong to

our profession as a privilege humbly to follow in the footsteps of Him whom we can call our common Master—who, clothed in human form, went about doing good, and delighted in relieving suffering humanity. Like Him, and influenced by such an example, it is our peculiar mission to heal the sick, to give sight to the blind, to make the deaf to hear, and the lame to walk; and from a bed of pain, of suffering, and of anguish, to raise up a first-born, and thereby to make a mother's heart to sing for joy. Allow me further to say, that we are not like those persons in the other professions who use the press, the platform, and occasionally even the pulpit, for their individual aggrandisement and professional promotion or advancement.

Neither is it ever found that the members of the medical profession parade or exhibit themselves before the public as others appear, robed in scarlet and ermine, with mace-bearers and trumpeters before them, and crying “They come! they come!” It has always been the business of this Society and its members to do their work privately and unostentatiously; and whether we be engaged in our common work here or are found in the halls and the chambers of the great and the rich, or in the houses and the garrets of the poor, we are invariably to be found pursuing our professional calling, and making it pre-eminently PRIVATE practice.

In this way we are obliged to throw ourselves, our reputations, and all our professional interests into the hands of those who have no knowledge of what we are engaged in, and no sympathies with us in the difficulties with which we are contending both by night and by day; and how often do we hear our good name and our best intentions assailed and libelled, and that even at the very time when we are engaged on behalf of the dearest interests of our gratuitous and uncharitable defamer, and this without redress. But he that “steals my purse steals trash, but he that filches from me my good name robs me of that which not enriches him, but makes me poor indeed.” Such being the case, we should be oftener found exercising more of the esprit de corps than is found occasionally to exist among us, seeing that we have but one common aim or object—the advancement of science, curing disease, and combating death. But, after all, there is nothing in life “so well becomes a man as a mild demeanour and manly courage,” springing from scholarly attainments and the mens conscia recti which must necessarily follow, and before which the walls of opposition must fall and the citadel be taken possession of. On the contrary, is not that miserable selfishness to be despised which prevents a man coming out and taking part in professional work, except when self-interest is the moving power. And when difficulties of any kind may arise, it is a pity to see the small man pursued before the wind and seeking shelter in his own retirement; to call this success and happiness is a burlesque upon the terms. I should rather take example from a higher, nobler, braver spirit, which,

with fixed purpose and determined will, breasts the storm, and, if needs be, mounts the hurricane; and as we follow him in his onward and his upward progress, we see him rising higher and higher, until at last he enters into that purer, calmer, clearer light above.

He lives too low who lives beneath the sky.

When I commenced to prepare this address I thought it would be my duty to bring before the notice of the Society some of the great achievements, progress, and improvements which have been attained within the last thirty or forty years in my own departments of medicine—viz., Midwifery and Gynæcology. But when I considered that I was to address a Society the members of which are practising in all the departments of medicine, I did not believe that this would be acceptable. Then I thought of reviewing the field of general medicine and the progress we had made in it during the same period; but I felt that the short time I had at my command was not equal to the task, and so I have fallen between these two great subjects, without satisfying myself, and feeling conscious that I have not satisfied my audience. I have, however, made an attempt, by throwing together a few crude and hurriedly-expressed thoughts, to prove that medicine occupies a very high (if not the highest) place among the learned professions. I might have easily done more had time permitted, as it is quite capable of proof that numbers of the medical profession occupy the very foremost ranks in advancing and sustaining the most important, because the most practical sciences, and that we accomplish more good work, in all countries and at all times, by ameliorating and improving man's condition, than is done by all others besides. And, finally, I think I may here claim for you what the public must eventually concede, to use the words of an able and accomplished thinker, that—

We live in deeds—not years; in thoughts—not breaths;

In feeling—not in figures on a dial;

We should count time by heart-throbs. He most lives

Who thinks most, feels the noblest, acts the best;

Life's but a means unto an end—that end

Beginning, mean, and end in all things—GOD.

Upon the motion of Dr. Harkin seconded by Dr. Wales the thanks of the meeting were conveyed to the President. It was resolved that the address be printed with the transactions.

The question of it being published in the local papers was discussed and on being put to the meeting it was decided not to publish in the daily papers.

R. F. Dill, President
16th December 1879

Second Meeting December 16th 1879

Present, Professor Dill President, Dr. J. W. Browne and Dr. Fagan, Core, Esler, Dempsey, McKee, Wales snr.

and jnr., Clements, Mackenzie, Graham.

Dr. Whitla proposed Dr. Frederick Wales, the President seconded his nomination.

Dr. Whitla proposed Dr. Crossle (Newry) and Dr. Clements seconded; Dr. Esler proposed and Dr. Dill seconded Dr. McHarry who were elected unanimously.

Dr. Browne showed an ovarian cyst removed from a patient.

Paper:¹ DR. J. W. BROWNE exhibited a beautiful specimen of ovarian cyst, which he had removed, some days previously, from a patient outside the hospital. He described the nature and supposed mode of origin of the cyst, and briefly related the points of interest in the clinical history of the case, but, as he would bring it up before the Society with other cases of ovariectomy which he had performed, he only asked them to look at the cyst. The patient was progressing very favourably, and he could say the case was decidedly successful.

Dr. McKee a thoracic aneurism.

Paper:² DR. M'KEE exhibited a ruptured aneurism, which was taken from a man who was found in Regent-street, Belfast, lying moaning. The gentleman who found him, believing he was suffering from intoxication sent for a policeman, who said he stooped over him and found a strong smell of drink. He had him removed on a car to the police-office, but on his arrival life was found to be extinct. The aneurism—not a very large one, situate on the ascending part of the arch of the aorta—burst into the pericardium, so that he found that space filled with clots and serum. The opening was about three-quarters of an inch in length. The man's occupation was what is ordinarily known as a plateholder in a shipbuilding yard; he, consequently, would have to lift and sustain heavy weights, which might, to some extent, account for its origin. Owing to the peculiar circumstances under which the man was found, he thought the case would be interesting to the Society—it being mistaken for a case of drunkenness.

DR. DEMPSEY thought it rare to find such a specimen without atheroma. He explained this by a reference to the occupation of the subject from which the specimen was taken.

The PRESIDENT thought it interesting from several points of view. He asked which of the coats had given way, or did all? If this latter, he would say it was a rupture from violence—if the former, he thought it should be put down as an aneurism.

He entered into the surroundings of the case, which were interesting, as it was supposed at first to be a case of drunkenness. Therefore, as coroner, he ordered a post-mortem examination, which revealed the specimen to be an aneurism, and he spoke at length of such a case being brought to the police-office instead of

¹ [Dublin Journal of Medical Science, 1880, v69, p251.]

²]Dublin Journal of Medical Science, 1880, v69, p251.]

directly to the Royal Hospital, where there was every accommodation for treatment, without the delay unavoidable at the police-office.

Dr. Clements showed a patient the subject of an encysted hydrocele of the cord.

Paper:¹ The patient, aged about eighteen, as far back as his recollection served, had observed this scrotal tumour, though he did not consider it anything unusual. His attention had been recently directed to it by the refusal of the regimental surgeon to pass him for the ranks of the army; and, in consequence, he came under his observation at the Belfast Dispensary. He considered the case worth showing to the members of the Society, both as a typical specimen of the encysted hydrocele, and on account of its comparatively large size. The spermatic cord can be distinctly felt passing out of the external inguinal ring, and its course traced for about two inches down to the posterior wall of the cyst, and can be again detected below, passing from the posterior wall of the cyst to the testis. The connexion of the cyst with the cord, both above and below, is definite and distinct, and the cyst is not extended along the cord in the form of a tubular prolongation in either direction. Four weeks ago he removed, through an aspirator needle, about one ounce and a half of hydrocele fluid from the cyst, which exhibited the usual characters of serum albumen, the cyst entirely collapsing. It has again collected, contains now, in his opinion, about two ounces of fluid, and it is his intention to again exhaust the contents of the cyst, and endeavour to excite adhesive inflammation by the injection of a small quantity of diluted tincture of iodine. Before doing so he was glad to have the opportunity of showing the members of the Society what he believed to be so typical a specimen of this affection.

Dr. BROWNE had two cases—one in a man, aged forty-two years, and the other a boy of eleven years. In both he passed a seton soaked in tincture of iodine, and in both there was a cure.

The PRESIDENT thought it was such cases as these that they were glad to see. They were cases which could be treated so well outside, and hence possessed greater interest to the mass of practitioners. He had treated several himself. The seton he used was a common woollen thread.

MR. FAGAN had seen and treated a good number of these cases. Once the diagnosis is clearly made out the path is simple. This was a well-marked case. All his cases were in children. He punctured, and allowed the fluid to get out into the tissues; a slight inflammatory action supervened, and the consequent consolidation caused such pressure as obliterated the cavity. He detailed various methods, and pointed out the importance of first seeing was there any connexion with the abdominal cavity. If this was the case, one should be

careful before using injections.

Dr. Whitla reported a successful case of herniotomy.

Paper:¹ He said:—Upon Oct. 4th I was called by a medical man to see a young muscular man, aged twenty-four years. His friends gave the following history:—In July last he discovered he had a hernia which was reduced by a physician, who fitted him with a truss which was so successful that in two months he threw it aside, the tumour having entirely disappeared. Upon Thursday, Sept. 29th, at 12 p.m., he awoke from an hour's sleep, having gone to bed fairly well, and smart vomiting occurred, with vague abdominal uneasiness, which passed off, leaving him suffering from obstinate and most painful vomiting, which continued in severity till he saw him. He had been attended by a physician whose attention had not been arrested by the suspicion of a hernia, and who treated him with preparations of bismuth and morphia. Upon the following Thursday (the 4th October) another medical man was called in, who discovered the presence of a hernia, and sent me an urgent message to come and see him. I found a tumour in the groin about the size of a small hen's egg, red, painful, and very tender, possessing all the characters of a small inflamed strangulated inguinal hernia. There was complete obstruction of the bowel for six days; there was great tympanites, and constant vomiting of offensive matter, and the patient seemed fast sinking. He had refused to go to hospital, and begged to be relieved by any operation which would give him a chance for life. I rather reluctantly consented to operate, as I feared it would be almost useless. Chloroform was administered by Dr. Quinn; and after a very gentle trial, which convinced me that taxis was unjustifiable, I operated. There was nothing of interest in the operation itself—the sac was very easily exposed, and finally I found it necessary to expose the bowel, which was almost black; the constriction was surprisingly tight, and the margin felt like a little ribbon of steel tied round the knuckle of bowel. One cut of the knife divided this, and I returned the bowel, not into the abdominal cavity, as I had mostly seen it done, but following the advice of my respected teacher, Professor Gordon, I simply left the knuckle of gut about the internal abdominal ring; its condition did not justify its return entirely within the cavity, and I thus hoped I might give my patient the additional chance, if the bowel sloughed, of an artificial anus. After the effects of the chloroform passed off, he passed wind by the anus; there was complete and speedy relief of all his symptoms. Free doses of opium, one grain every four hours for first day, and half this quantity the second. The bowels did not act for five days; then they did so naturally, and in three weeks he had a truss fitted on, and is now at his business—a draper's assistant. I would hardly have considered it

¹ [Dublin Journal of Medical Science, 1880, v69, p252.]

¹ [Dublin Journal of Medical Science, 1880, v69, p253.]

worth bringing under the notice of the Society but for a few points of interest to which I would briefly refer—first, the period of strangulation was very long for a good recovery to follow; and, secondly, it is the fashion to bundle off all such cases to hospital, and I have no hesitation whatever in asserting, had this patient been removed to hospital, he could hardly have survived; the removal and jolting of a hernial subject in his condition must almost necessarily be followed by fatal results. I fully appreciate Dr. Fagan's remarks about the death-roll being increased by the abuse of the taxis. This leads me to look at an entirely new aspect of the hernial question.

Looking at it purely from a “psychological” point of view, one could easily see why the death-roll was so increased. I would not insinuate the least blame to the general outside practitioners; and keeping in mind the complex elements of human nature at play in these cases, no one could blame them. A young man outside hospital will not send in a case of hernia for operation until he has demonstrated fully to himself that it will not go up, for if reduced on admission there will be to his mind some amount of stigma thrown upon him by the ignorant patient and his friends, and the consciousness of this tempts him to try the taxis to the utmost; and though this is but an evidence of weakness from the nature of matters, it must always exist, and should be recognised (though perhaps humiliatingly) in the treatment of the question. I refer chiefly to the hernia cases occurring amongst the poorer classes—hospital cases. If hospital surgeons would agree to visit, before removal, all hernia cases with the ordinary practitioner or poor law medical man, I think hernia would be more satisfactorily dealt with.

Du. FAGAN thought it pleasant to see a success after so long strangulation. There could be no doubt whatever about the wisdom of the procedure. Surgeons now all recognise the advisability—nay, the necessity—of not returning the bowel within the abdominal cavity in cases where the bowel is very much strangulated. He detailed cases illustrative of this. He spoke at some length about the conduct of practitioners outside in using the taxis to so great an extent as they generally did, thus swelling their hospital death-roll.

Dr. J. W. BROWNE said he thought the sac should always be opened in hernia of many days' strangulation. He had operated upon his nineteenth case of hernia three days since.

DR. DILL said taking these two operations, having been performed outside the hospital—the case of hernia and the one of ovariectomy—they supported a view he always held that, without disparaging hospital practice, he could have far better results outside. He quoted, from Savory and others, statements about the antiseptic treatment which illustrated his views, and referred to the condition of the atmosphere in large hospitals in densely populated districts, and contrasted the advan-

tages offered by the patient's home and its surroundings, however humble.

Dr. Browne read an interesting paper upon several cases of unusual hernia.

Paper:¹ SINCE my appointment as surgeon to the Belfast Royal Hospital in 1876, I have operated upon, in private and hospital practice, twenty cases of strangulated hernia—viz., twelve cases inguinal, seven femoral, and one umbilical. Of my twenty cases eleven died. Upon looking over my case-book, I find six cases were almost moribund before being brought under notice.

I may just mention that from the 1st January, 1850, to the 31st December, 1875, ninety-nine cases of strangulated hernia were operated upon at the Belfast Royal Hospital, of which thirty-six died. My patients ranged in age from ten weeks to eighty-four years.

In the after-treatment of all the cases, with the exception of those which were moribund, opium and ice-poultices, or ice-bags, were used.

Immediately after the operation the patient is at once put upon opium, dose being moderated according to the age; and ice-poultices—i.e., ice broken up into small fragments, and mixed with a quantity of sawdust—or ice-bags, which I prefer, are placed over the abdomen, a piece of lint intervening between the bag and skin. At the same time the patient is kept upon spoon diet. The ice and opium are continued as long as any pain or tenderness upon pressure over the abdomen is experienced. I have great faith in the application of ice to the abdomen where symptoms of peritonitis threaten after operations for hernia, and recently I have used ice-bags in all cases of injuries of abdomen in the early stages, at once discontinuing their use should any symptoms of depression occur. A practical paper, “On the Local Use of Cold in Abdominal Inflammations,” appeared in *The Lancet*, February 26, 1876, by Dr. Eade, of Norfolk, in which he advocates the local use of cold in preference to warm applications in nearly all cases of inflammation of the abdomen.

Dr. Eade considers “the modus operandi is to abstract heat, to benumb exalted sensibility, and to contract the dilated and semi-paralysed vessels; and its especial effects have seemed to be to diminish abdominal distension, to control the volvulus writhings of the bowels, and thereby to relieve both pain and tenderness.”

At the end of five days I like to get the patient's bowels to act, and with that view cease the use of opium, provided the pulse and temperature are not much above normal. As a rule, with the cessation of the opium the bowels act spontaneously, and if they do not do so in twelve hours, I order an enema of turpentine and castor-oil, as, no doubt, frequently the safety of the patient depends upon procuring evacuations from the

¹ [Dublin Journal of Medical Science, 1880, v70, p71.]

bowels. To my mind it is very important that we should obtain an evacuation of the contents of the intestines in all cases of hernia after a certain period, but especially in elderly and fat people should we be doubly anxious, as Mr. Jordan, of Birmingham, in *The British Medical Journal*, April 26, 1879, states that the cause of death after hernia operations is frequently due to fatty change and failure of the muscular wall of the gut. Mr. Jordan shows that, upon post mortem examination of some of his fatal cases of hernia, the intestinal canal was singularly and uniformly yellow, and everywhere enormously distended; and the muscular wall, when microscopically examined, was seen to have undergone fatty degeneration.

In some cases where the patient suffered much from flatulent distension about the third day, in addition to using turpentine stupes to the abdomen, a rectal tube has been passed with much benefit. When chloroform has been the anæsthetic used, troublesome symptoms after the operation are nausea and vomiting. I have always prescribed, with much benefit, a cup of very strong tea—a practice advocated by Dr. G. H. B. Macleod, in *The British Medical Journal*, July 8, 1876. In all my cases the sac was opened, with the exception of one case of femoral hernia, to be alluded to further on.

When the strangulation is of several days' duration—and it is in such cases, as a rule, we are called upon to operate in hospital practice—I like to open the sac and see the contents, also where the symptoms of strangulation from the very first have been very acute. Although the stricture is frequently external to the sac, yet the neck of the sac itself may form the stricture. Adventitious bands may remain inside; and as length of time is not an absolute criterion as to the state of the contents of the sac, but rather the tightness with which the bowel has been caught, you cannot tell with certainty when to open the sac, and when to leave it unopened. In all cases of femoral hernia I would be inclined to open the sac, as it is in this form of hernia we so frequently meet with omental sacs, strangulating the bowel.

The late Mr. Maunder, in a clinical lecture at the London Hospital (*Lancet*, January 13, 1877), states that surgeons are pretty well agreed that it is immaterial whether the sac be opened or not in femoral hernia.

In the division of the seat of stricture in all the cases, with the exception of one, where I accidentally wounded the intestine, I used the hernia knife introduced into practice by Dr. Alexander Patterson, Surgeon to the Western Infirmary, Glasgow, and described by him in *The Glasgow Medical Journal*, February, 1873. Dr. Patterson, in describing his knife, says:—"It differs from Sir At Cooper's simply in the blunt, pointed part of the knife having a quarter turn given to it, so that the flattened point passes more readily under the stricture, while its breadth flattens and pushes the gut

aside as the cutting part of the blade follows."

A knife somewhat upon the same principle is the one invented by Dr. B. W. Richardson, of the Adelaide Hospital, Dublin, and described by him in *The Dublin Quarterly Journal*, November, 1869.

I have found Dr. Patterson's knife especially serviceable in operating upon femoral hernia, where the stricture is very tight; the point of the instrument being slightly wedge-shaped, is readily insinuated under the stricture. It will also be found useful in cases of inguinal hernia, where the stricture is deeply seated, and a large mass of intestine is prolapsed, for it is in such cases that we dread wounding the intestine. Here, by placing the forefinger at the point of stricture, the intestines are pushed aside, and the knife can be slipped along the palmar surface of the finger, and the stricture divided; the blade being inserted with the cutting edge upwards, there is no risk of the bowel being wounded. After division of the stricture I invariably pull down into the wound a portion of bowel from the abdomen, in order to see that the intestine is perfectly free, and have a view of the strictured portion. When about to return the bowel into the abdominal cavity, no great pressure should be used; and in three of my cases the hernia knife was re-introduced to enlarge the opening. It is always pleasant to feel the intestine, as it were, glide away. After all the intestine has left the sac, I follow the practice inculcated by my distinguished teacher, Professor Gordon, Belfast—"Never push the finger up into the abdominal cavity; satisfy yourself that the canal is clear, that is quite sufficient."

You will remember that I told you six cases almost moribund had been operated upon. You may reasonably ask me—Why operate in such cases, and thus increase your percentage of deaths? My answer is that I have seen cases operated upon which were deemed quite hopeless, nevertheless they recovered; and I well remember a woman, aged seventy-six, being admitted into the hospital in 1868, when I was House Surgeon, suffering from a strangulated femoral hernia of seven days' duration; she was very weak—in fact, almost pulseless. Mr. MacCormac, now of St. Thomas's Hospital, London, operated, and the patient recovered. This case made such an impression upon my mind that in almost all cases of strangulated hernia, no matter how long the bowel had been constricted, I would be inclined to operate, and give the patient the chance of recovering even with an artificial anus.

Sir A. Cooper, in his *Surgical Lectures*, states that "if the pulse be so small as to be scarcely perceptible, and the countenance anxious and sunken, no time is to be lost; but even under these circumstances, and with hiccough superadded, I have known the operation succeed." And in the next paragraph he says:—"Indeed there is scarcely any period of the symptoms which should forbid the operation."

Sir James Paget, in his *Clinical Lectures and Essays*,

when speaking of strangulated hernia and the various symptoms demanding operation, states at p. 126.:—"A patient must not be allowed to die with a strangulated hernia, if by any means whatever the strangulation can be relieved, and you must not be averted from the operation by any consideration of the number of deaths that follow it." And again, at p. 148, Sir James says:—"I have had to operate on patients already dying; I could not refuse to operate, for I could not be certain that it would be useless."

Having the opinions of two such distinguished men to guide us, I think we are justified in operating in all cases of strangulated hernia, no matter how hopeless the case may appear.

My last eight cases were performed with rigid anti-septic precautions, and I must bear my humble testimony to the great benefits it confers upon the surgeon, and also upon his patients.

I do not intend to give you a detailed history of my twenty cases, but only a short account of seven or eight, which, either differing from the usual condition of matters or from the occurrence of some rare complications, may interest you.

CASE I.—Congenital Strangulated Inguinal Hernia in a boy, aged ten weeks; Operation; Recovery.

M. M., aged ten weeks, a weak, delicate child, was admitted into hospital on 31st August, 1876, suffering from a strangulated inguinal hernia, of three days' duration. Upon examination I found a right inguinal hernia, strangulated; the abdomen was very tympanitic, and tender upon pressure. The little fellow vomited all food, and the bowels had not been opened for three days.

I at once ordered the child a warm bath, and tried the taxis. Following out the practice advocated by some surgeons, especially in strangulated hernia in children, of elevating the pelvis and legs, I was unsuccessful; at once operated; the usual incisions were made in the axis of the hernial tumour; the sac opened; the hernia proved to be of the congenital variety, and contained intestine and omentum.

Owing to the age of the child, I had extreme difficulty in introducing the tip of my little finger into the canal, the stricture being at the internal abdominal ring. When the stricture was divided, as customary, I pulled down a portion of intestine to view the seat of stricture.

The child suddenly made an expiratory effort, and down came two feet of intestine. The mass was so large I had great difficulty in manipulating it through the canal, and before succeeding it was necessary to enlarge the opening, and to wrap the prolapsed intestine in fine cloths wrung out of warm water. After the application of the warm water, the intestine seemed, as it were, to shrink up, and reduction was easily effected. The youngster made an uninterrupted recovery.

Remarks.—At the time I operated (August, 1876) I could

not find recorded a successful operation in a patient so young. Mr. Erichsen (*Lancet*, 1872), I find, operated upon a child six weeks old, but the child died at the end of a month from a low form of peritonitis.

Within the last two months I saw reported in the journals a case of successful operation for strangulated hernia in a child fourteen days old. As regards the elevation of the pelvis in conjunction with the taxis, I once heard a distinguished London surgeon state that he had never found it necessary to operate for strangulated hernia in children—that he was always able to reduce the gut by taxis. However, in my case elevation got a good chance, but failed.

Since the occurrence of this case I have frequently found when a large mass of intestine was down, that by enveloping it in cloths or sponges wrung out of warm water, the volume of the prolapsed portion was almost at once reduced in size, and easily returned by taxis.

CASE II.—Strangulated Femoral Hernia; Omental Sac; Death.

A woman, aged fifty years, was admitted into hospital under my care, suffering from a right strangulated femoral hernia; symptoms of strangulation had continued four days. Upon examination I found a tense femoral hernia in right groin. Administered chloroform; tried taxis unsuccessfully; at once operated. The usual incisions were made, the fascia propria exposed, then the sac. My colleagues requested me to divide the stricture external to the sac; I did so, and by very gentle taxis emptied the sac. After the operation the symptoms of strangulation continued, and in three days the patient died.

Upon post mortem examination we found general peritonitis, and above the femoral opening a small mass of omentum, in the centre of which was concealed a piece of intestine about the size of the tip of the forefinger.

Remarks.—Had I the luck to open the sac in this case, the "omental sac" would have been found, and the intestine easily liberated. It is in cases of femoral hernia, as I previously mentioned, that we most frequently meet with omental sacs, and since the occurrence of this case I always recommend the opening of the sac in femoral hernia.

The seat of stricture, as a rule, in femoral hernia is to be found at the falciform process of the saphenous opening—Hoy's ligament—and not at Gimbernat's ligament. This fact has always been taught by Professor Gordon, and was long since pointed out by Sir A. Cooper. According to Cooper, the stricture may be found both at Hey's ligament and under the crural arch of Poupert's ligament.

A practical point to observe in operating upon cases of femoral hernia is the layer of adipose tissue which lies between the fascia propria, or sheath of the femoral vessels, and the sac. Sir A. Cooper states that he has known the fascia propria to be mistaken for the hernial

sac. In fat subjects divide the strictures until you come upon the “fatty layer,” and you have the sac underneath.

CASE III—Strangulated Inguinal Hernia; Accidental Wound of Intestine; Recovery.

W. R., aged fourteen years, admitted August, 1879, suffering from a right strangulated inguinal hernia. He had been in hospital twelve months previously, suffering from strangulation of the intestine, when the taxis was used successfully. He had not worn a truss, although one was applied before he left hospital.

Upon admission a very tense inguinal hernia, dull upon percussion, was found. An omental hernia was diagnosed, owing to the dulness. The symptoms of strangulation were urgent, and immediate operation, after an unsuccessful trial of taxis, was determined upon. The usual incisions. Opened sac; it contained a large mass of intestine, and no omentum. The seat of stricture, at the internal abdominal ring, was divided with difficulty. When we endeavoured to replace the intestine, the opening was considered too small; and when introducing Sir A. Cooper's knife to enlarge the opening, I wounded the intestine. Almost immediately arterial blood came in a good flow from the wound. Upon examination of the gut an incised wound, half an inch long, but only involving the peritoneal and muscular coats of the intestine, was found; the mucous membrane of the bowel was prolapsed, as it were, to fill up the gap. The vessel was easily secured by Pean's artery forceps, and torsioned; no suture was used. After the operation I at once commenced the use of opium, and applied ice-bags over the abdomen; stopped opium upon sixth day, when bowels acted spontaneously. The boy's temperature and pulse were never above normal, and he made a rapid recovery.

Remarks.—Wound of the intestine, a very serious accident, is not of frequent occurrence. Cases are recorded where the most skilful surgeon has accidentally incised the intestine, and no doubt the gravity of the injury depends upon the fact whether or not the wound penetrates the cavity. Lawrence states:—“A superficial wound—that is, one which does not penetrate the cavity—is of no consequence; the intestine may be returned without the slightest fear of unpleasant results.”

In my case the wound did not penetrate, and I simply restrained the bleeding. In operating upon this case, I used Sir A. Cooper's hernia knife, and I fully believe, had Patterson's or Richardson's knife been used, the accident would not have occurred. You are all aware how it is recommended in works on surgery to introduce Cooper's knife—lying flat upon the forefinger until the seat of stricture is reached, then to turn the cutting edge upwards. You will remember I told you a large mass of intestine protruded, and the stricture being very deep at the internal ring, it was scarcely possible to see what was being cut. The intestine slightly overlapped my finger, and when re-introducing Cooper's

knife in the manner recommended, the gut was wounded.

I think that Patterson's knife is specially of service in cases where a large mass of intestine is in the sac, and where the seat of stricture is deeply situated. The forefinger acts as a guide for it to the point of stricture, and at the same time pushes the intestines aside. The knife is introduced along the finger with cutting edge upwards, and by keeping the blade of the knife upon the centre of the finger, and, just before dividing the stricture, requesting your assistant to make the parts at the neck of the sac tense by gently pulling down the prolapsed bowel, all danger of wounding the gut, in my opinion, is avoided. As regards the diagnosis of this case, you see a mistake was made—from the dulness of the tumour it was thought to be an epiplocele. From my limited experience I consider it almost impossible to accurately ascertain the contents of the sac before operating.

CASE IV.—Strangulated Inguinal Hernia; Intestine abraded of its Peritoneal Coat; Recovery.

J. L., aged thirty-six, admitted to hospital June, 1879, suffering from a large scrotal hernia upon right side. Upon consultation, immediate operative interference was deemed necessary. Chloroform administered, and the usual incisions made. Opened sac; it contained four feet of small intestine of a good colour, with the exception of the portion at seat of stricture, which was very dark. After division of the stricture I endeavoured by gentle taxis to reduce the bowel, but, owing to the large mass, was unsuccessful. Sponges wrung out of warm water were then applied, and the volume of the mass almost immediately became reduced, and at the expiration of ten minutes all the hernia was replaced. Just before the last portion of gut was returned I noticed that it was denuded of its peritoneal coat to the extent of a square inch. The part was washed with a weak solution of carbolic acid, the peritoneum spread out over its former situation, and reduction proceeded with. The patient never had a bad symptom, and left hospital at the expiration of sixteen days.

Remarks.—It is rare to have such a mass of intestine prolapsed as was in this case. The case teaches us to be very careful in the use of the taxis when endeavouring to replace the bowel, and it also shows how much handling the intestine will frequently bear without any ill results.

CASE V.—Strangulated Umbilical Hernia mistaken for a Carbuncle.

Mrs. R., aged fifty-seven, was sent into the hospital, May, 1877, reported to be suffering from a carbuncle of the abdomen. My resident pupil was so confident that the poor woman was labouring under a carbuncle that he had strips of soap plaster ready cut to commence treatment at the hour of my visit. Casually placing my hand over the tumour, which occupied the umbilical region, I felt distinct gurgling when a little pressure

was made. The existence of a hernia was now suspected; and, upon questioning the patient, I ascertained she had been vomiting incessantly for seven days, and that the bowels had not acted for five days. She also told me she had noticed a tumour the size of a walnut occasionally, at the umbilical opening, during the past few years, but that it had increased to the present size (about the size of half an orange) one week since. Certainly the tumour much resembled in appearance and coloration a carbuncle. I now saw we had a case of strangulated umbilical hernia to deal with. Tried the taxis, and immediately the tumour became reduced in size by a half; but there remained a hard mass which could not be replaced. The patient being very weak and evidently sinking, I summoned a consultation, when it was decided to operate at once. Made a longitudinal incision over the hernial tumour, opened the peritoneum, and found a mass of omentum highly congested. Upon gently raising the omentum a portion of intestine was seen to be glued to its lower surface. The adhesions between intestine and omentum were easily broken down. The umbilicus was incised in the median line upwards, and the omentum left in situ. The patient died in twenty-four hours.

Remarks.—This case teaches us to be very careful in diagnosis. We all know how rare it is to find a carbuncle upon the anterior portion of the body—still they do appear there; and a tumour occupying the umbilical region should lead us to inquire into its character. In Lawrence's treatise on "Hernia" (p. 589) you will see recorded cases of fatty tumours on the linea alba which resembled ruptures, and were operated on as such.

CASE VI.—Strangulated Scrotal Hernia diagnosed to be a Hæmatocele, and tapped.

A. R., aged fifty years, was brought to the hospital several months since by a medical man, who informed the House Surgeon that the patient was suffering from a scrotal tumour—probably a hæmatocele—which he had tapped with the ordinary hydrocele trocar and cannula. As very little blood flowed he considered the cavity of the tunica vaginalis to be filled with blood-clots. The patient upon examination presented a rounded tumour of the scrotum the size of a child's head; the skin covering it was very dark, and at a distance it very much resembled a hæmatocele. In addition, the tumour was dull upon percussion, very heavy, and not translucent. The right inguinal canal was occupied by a swelling which could only be felt upon very deep pressure.

At the lower part of right side of scrotum there was a puncture, through which a dark fluid oozed, having a fæcal odour. The patient when seen by me, five hours after admission, was almost pulseless and cold. Before my arrival the House Surgeon had applied warmth and given stimulants. The case was very puzzling at first sight. There was no history of injury to the scrotum. I happened to examine the man's abdomen, and found

that he had been recently blistered and treated for "inflammation of the bowels." He denied ever having a rupture and had not worn a truss, but told me that twelve days since he was suddenly seized with vomiting and pain in the abdomen. At the same time he observed the "lump" in the scrotum. A medical man was called in, who told him he had inflammation of the bowels and stomach.

At the expiration of twelve days, the vomiting and other urgent symptoms continuing, a second medical man was sent for, who now had all his attention directed to the scrotal tumour, which he diagnosed to be a hæmatocele, and punctured it. The same afternoon the patient was sent into hospital.

A consultation being summoned, the diagnosis, strangulated inguinal hernia, was come to, and although no doubt the intestine was gangrenous and the patient very low, we thought an operation might give him a chance.

The usual incisions were made. Opened the sac and found upwards of four feet of intestine in the scrotum. It was quite gangrenous, and ruptured at several points. We saw the opening which had been made by the trocar. The poor fellow only survived the operation eight hours.

Remarks.—At first sight the case much resembled one of hæmatocele, and, in addition, the fulness along the inguinal canal led to the belief that possibly it might be a case of hæmatocele of the tunica vaginalis and diffused hæmatocele of the cord. However, when the history was obtained all doubts regarding the diagnosis were at an end.

As bearing upon this case you will see recorded in Curling's Treatise on "Diseases of the Testis" a case related by Sir A. Cooper, in which a man was brought into St. Bartholomew's Hospital suffering from a scrotal tumour, which was considered a hernia. Owing to some symptoms of strangulation being present an operation was performed. The sac opened, and no intestine found; blood, "partly fluid and partly grumous, burst forth." The case was a hæmatocele of the tunica vaginalis and cord.

CASE VII.—Displaced Inguinal Hernia.

A. J., aged thirty-eight, admitted into hospital 18th September, 1879, suffering from a strangulated hernia. We found that he had suffered for years from a reducible hernia, and had worn a truss. One week since he noticed the hernia had a constant tendency to slip down behind the pad unless carefully watched.

To-day when at work a larger lump than usual suddenly appeared behind the pad. He was at once seized with very urgent symptoms of strangulation, and eight hours afterwards was sent into hospital. Upon looking at the hernial tumour as he lay in bed, I was at once struck by its peculiar shape. Upon examination we found the left inguinal canal and upper part of left scrotum occupied by the hernia, and, in addition, there

was a swelling quite exterior to the internal abdominal ring, situated in the abdominal wall. I now suspected we had a case of displaced hernia to deal with, as a similar case occurred in the hospital when I was House Surgeon.

The patient when visited felt easy—temperature, 98.6°; pulse, 80; no vomiting—in fact, all the urgent symptoms had disappeared since his admission. Ice-bag was applied to the hernial tumour, and opium given. Six hours following admission vomiting recommenced, and, after consultation, I operated. Usual incisions were made; came down to sac, opened it, and introduced my forefinger along the intestine to feel for seat of stricture, but was surprised to find my finger went into a space, which I at first considered to be the abdominal cavity. I now drew down intestine, and as it came outside the scrotum the tumour exterior to the inguinal canal was seen to disappear. It was now quite apparent that my finger had been in a space between the abdominal muscles occupied by the hernia. Now, following the intestine very deeply, a stricture was found at the internal abdominal ring. It was divided and the hernia reduced. The intestine was of a dark claret-colour, and upon its surface several blood-clots were found—the result of efforts at taxis before admission. The patient died upon the fourth day from a low form of peritonitis. Upon post mortem examination I found general peritonitis and a sac between the internal oblique and transversalis muscles, which had been occupied by the hernia.

Remarks.—Cases of displaced hernia are rare. As you are aware they may occur when you have a hernia complicated with an undescended testicle, the testicle occupying the canal and preventing the intestine passing into the scrotum. The intestine, being prevented from entering the canal, then stretches the neck of the vaginal process into a sac placed between the tissues of the abdominal walls, either upwards or downwards, between the skin and muscles, the muscles themselves, or between the muscles and internal abdominal fascia, forming the intra-parietal, intermuscular, or interstitial sac—hernie en bissac of the French, additional sac of Birkett (Bryant).

Although an undescended testicle appears to be the most common cause of this form of hernia, it may also be produced by a badly fitting truss, which, pressing only upon the external abdominal ring, allows the intestine to descend into the inguinal canal. It cannot escape at the external abdominal ring, and, as time proceeds, it gradually stretches the neck of the tunica vaginalis before it, forming an “intra-parietal” rupture.

In my case, no doubt, the poor fellow had worn a badly fitting truss for years, and instead of the pad pressing upon the internal abdominal ring and canal, it had pressed upon the external ring, and permitted of the gradual development of the additional sac.

CASE VIII.—Strangulated Congenital Inguinal Hernia in

a girl; sac contained omentum, intestine, and the Left Ovary.

P. A., aged ten years, was admitted into hospital 12th August, 1879, suffering from a strangulated inguinal hernia, the symptoms of strangulation having existed for thirty-six hours.

Her mother stated that the rupture was noticed shortly after birth, but gave no trouble until the child was three years of age, when it became larger and painful at intervals, but was always easily reduced. When the child was five years of age the hernia became strangulated, and the mother was unable to return it. She was admitted into the Children's Hospital, where it was reduced, and was discharged wearing a properly fitting truss. After a time the truss was left off, and the rupture came down occasionally as before, up to March, 1878, when symptoms of strangulation again occurred. She was admitted into the Royal Hospital under my care, when reduction was easily effected, and she left hospital with a truss applied. The use of the second truss was discontinued, but the hernia did not again come down until the 10th August, 1879.

When admitted into hospital on the 12th August, 1879, I found a tumour at the external abdominal ring as large as a hen's egg, tense to the feel, and painful. Symptoms of strangulation being urgent, the patient was put into a warm bath, had an opiate, and taxis tried unsuccessfully. Chloroform was now administered; taxis a second time being tried without success, the operation was proceeded with. The sac was opened, and instantly a quantity of omentum, very much congested, came into view; behind the omentum lay a small piece of intestine. The stricture, which was very tight, was now divided; the intestine returned. The omentum, measuring four inches long and two inches wide, owing to its congested appearance, was ligatured with a double catgut ligature, and cut off close to the neck of the sac; the pedicle and ligature were then returned into the abdomen. Upon now examining the sac I discovered at its upper part a structure much the size of a small lymphatic gland. When this was carefully examined we found it to be the left ovary and broad ligament. It was some time before an opinion was pronounced, and it was only after the parts had been drawn gently down that we satisfied ourselves regarding the identity of the ovary and broad ligament. The ovary was healthy in appearance, not being in the slightest degree congested, and it was returned into the abdomen. The entire operation was performed antiseptically. Ice-bags were applied to the abdomen after the operation, and opium in small doses administered. The pulse and temperature were never above the normal standard until the twelfth day, when a small abscess formed in the abdominal wall; this was at once incised, and the child was discharged in three weeks' time, wound cicatrised, and wearing a truss.

Remarks.—Cases of hernia in which the ovary has been

found in the sac are rare, no reference being made to it in the surgical works of Holmes, Erichsen, Fergusson, Paget, Bryant, Skey, or Gross. Lawrence mentions cases as having occurred in the practice of Pott.

At a meeting of the Medical and Chirurgical Society in 1864, Mr. Coote mentioned a case which had occurred at St. Bartholomew's Hospital. A woman was admitted into the hospital with a swelling in the left groin, and suffering from the symptoms of a strangulated hernia. An operation was performed. When the sac was opened it was found to contain some thickened omentum and the left ovary. At the same meeting Mr. C. Hawkins stated he had met with two cases in which the ovary was found in the hernial sac.

In the Bellevue Hospital Reports, 1870, twelve cases of ovarian hernia are recorded by Dr. Hamilton, which were operated upon before a diagnosis was made.

In the "Transactions of the London Obstetrical Society" a case is recorded by Dr. Alfred Meadows.

In the American Journal of the Medical Sciences for October, 1877, Dr. Balleray, of New Jersey, reports a case of strangulated hernia which was operated upon, when neither intestine nor omentum was found, but the left ovary was lying near the lower part of the sac. Dr. Balleray also discusses the propriety of leaving the ovary in the sac, or returning it into the abdomen after division of stricture. He says:—"The rule by which the surgeon is governed in the management of strangulated intestine, or omentum, is, I think, applicable to these cases." He considers when the ovary is but slightly congested it should be returned into the abdominal cavity. "But in cases in which, from long continuance of the strangulation, or excessive tightness of the stricture, the tissues of the ovary either are or are likely to become gangrenous, removal of the organ is, in my opinion, the proper course to pursue."

Those of you who have been reading The Lancet must have noticed in the "Transactions of the London Obstetrical Society," published in The Lancet, Oct. 11, 1877, a case of congenital inguino-ovarian hernia, reported by Dr. T. Chambers. The patient had noticed swellings in the groins for many years, and as they were occasionally subject to pain from knocks and injuries, it was determined to remove them, as they could not be returned into the abdomen. After removal they were subjected to microscopical examination, and found to be glandular organs, presenting the structure, not of ovaries, but of imperfectly developed testicles.

In the editorial remarks upon Dr. Chambers' case it is stated:—"Cases of inguinal hernia of the ovaries are rare; cases of congenital inguinal hernia of these organs are much more rare—so-much so, indeed, that any case recorded as such should be looked upon with the gravest suspicion, unless positive anatomical proof of it be brought forward."

There is no doubt but my case was a congenital

inguinal hernia, as the mother had noticed the protrusion almost from the child's birth.

In the examination of the contents of the sac I had the benefit of the experience of two distinguished Scotch medical men, who happened to be present at the operation, and we were all agreed upon the fact that, after the intestine and omentum were returned, there still remained in the hernial sac the left ovary and broad ligament.

Those of you who take an interest in the subject of ovarian hernia will see in the "Biennial Retrospect of Medicine and Surgery" (Sydenham Society) for 1871-72, a very practical paper upon the various varieties of the hernia, its complications and treatment, drawn up by Mr. Waren Tay, of the London Hospital.

John Fagan, Chairman

The Third Meeting was held upon December 30th 1879

Present, Professor Dill M.D., Dr. Fagan, Dr. J. W. Browne, Dr. John Moore, McConnell, Dempsey, McKee, Withers, Mackenzie, Clements, Speer, Esler, Workman, and Whitla. O'Malley, O'Neill.

Dr. Speer withdrew his paper upon "Medico-legal evidence at coroner's inquests".

The Code of Ethics, Table of Fees and Rules of the Society as revised and altered by Council were submitted to the meeting and after discussion some slight alterations were made and it was agreed to have [them] reprinted immediately and bound with the transactions.

A CODE OF MEDICAL ETHICS AS DRAWN UP AND ADOPTED BY THE ULSTER MEDICAL SOCIETY Revised December 30th, 1879

SECTION I.

DUTIES OF PHYSICIANS TO THEIR PATIENTS.

A Physician should ever remember that the health and safety of his patients depend materially upon his assiduity and skill; and should also study to unite kindness with firmness, being courteous while exercising due authority.

1.—Secrecy and delicacy, when required by peculiar circumstances, should be strictly observed; the obligation of the former extends beyond the period of professional services. None of the privacies of personal and domestic life—no infirmity of disposition or flaw of character, observed during professional attendance—should ever be divulged, except when such disclosure is imperatively required.

2.—All unnecessary visits are to be avoided—yet the patient is not to be abandoned because the case is deemed incurable; and, while a Physician should not

Ulster Medical Society
Session 1879–1880
President Robert Foster Dill

be forward to make gloomy prognostications, he must not esteem any case of too trivial importance; nor should he fail to embrace the opportunity, which he not unfrequently enjoys, of promoting and strengthening the good resolutions of his patients.

SECTION II.

DUTIES FOR THE SUPPORT OF PROFESSIONAL CHARACTER.

There is no profession from the Members of which greater purity of character and a higher standard of moral excellence are required than the Medical; nor can any scientific attainments ever compensate for the want of correct moral principles. It is, therefore, incumbent on its Members that they should be

1.—Temperate in all things—the practice of Physic requiring the unremitting exercise of a clear and vigorous understanding.

2.—Members should avoid, in the presence of non-professional persons, all remarks reflecting on the character of the profession, or those engaged in it.

3.—No Member should resort to public advertisements (except in case of removal), to the issuing of private cards or hand-bills, offering advice and medicine to the poor gratis, nor publish reports of cases or operations in the daily prints, nor suffer such to be made; he should not invite laymen to be present at operations, or boast of cures and remedies. Such is the ordinary practice of Empirics, and highly derogatory to the dignity of the profession.

4.—No Member should give testimonials in favour of any patent or proprietary medicines, or in any way recommend their public use.

5.—No Member should enter into compact with a Druggist or Apothecary to prescribe gratuitously, and, at the same time, share in the profits arising from the sale of the medicines.

SECTION III.

DUTIES OF PHYSICIANS TO EACH OTHER.

In cases of personal affliction, medical men are peculiarly dependent on each other; and kind offices and professional aid should always be cheerfully afforded; therefore,

1.—All Practitioners, with their wives and children, are entitled to the gratuitous services of any one or more of the faculty residing near them; if called to a distance, expenses should be paid.

2.—When, during sickness, affliction, or absence from home (not exceeding one month), one Practitioner has entrusted the care of his practice to a professional friend, the latter should not make any claim on the former, or the patient, for his services; but should, in all things, be the *locum tenens* of the absentee, save in cases of Midwifery, not previously arranged for.

3.—When a medical man has officiated, for another, and the ordinary Practitioner has resumed his exclu-

sive attendance upon the case, the former shall, on no pretext, make friendly calls upon the patient, without the consent of the ordinary medical attendant.

4.—A Physician, being a friend of the family, should avoid visiting when aware that any member of the family is under the care of another medical man.

5.—When a Practitioner is called on an emergency by a family usually attended by another, he should, when the emergency is provided for, meet the ordinary Practitioner, and, after one consultation, resign the case into his hands; but is entitled to charge the family for his services.

6.—When a Practitioner is consulted by a patient whom he has previously attended as the officiating friend of another, he should decline visiting, unless the patient has determined on changing his medical attendant; and if so, he will be justified in taking charge—intimating, in all cases, the same to the former attendant.

7.—When a Practitioner is called to attend at an accouchement for another, he should in all cases, but the one provided for in Rule 2, Section III., be entitled to receive a fair proportion of the fee; and when the delivery is completed, or the arrival of the pre-engaged accoucheur, he should resign the further management of the case, unless with the consent of the ordinary attendant.

SECTION IV.

DUTIES IN REGARD TO CONSULTATION.

A Physician who is called upon to consult should observe the most honourable and scrupulous regard for the character and standing of the Practitioner in attendance. No hints or insinuations are to be thrown out by the Consulting Physician; and he should also refrain from any extraordinary attention or assiduity for the purpose of gaining applause, or ingratiating himself into the favour of families or individuals.

1.—No Member should, on any pretext, meet in consultation persons practising medicine who do not possess a legal qualification.

2.—When two Practitioners attend in consultation, and the period of meeting having been fixed, one of the two neglects punctuality—thus wasting the time of the other—the latter shall be expected to wait ten minutes, and may then visit the patient, provided a note or message be not sent.

3.—In consultations, the attending Physician should introduce the consultant, and, if necessary, be the first to examine the patient; and the ordinary attendant should communicate the directions agreed upon to the patient or his friends, as well as any opinions which it may be thought proper to express. No opinions or prognostications should be delivered which are not the result of previous deliberation or concurrence; and all discussions being held as confidential, neither by words or manner should any of the parties

assert or insinuate that any part of the treatment pursued did not receive his assent; the responsibility must be equally divided, and the consultant should hold no conversation with the patient or his friends with reference to the case, except in the presence of the usual attendant.

4.—When a Practitioner takes charge of a case for his friend, and it appears necessary to change the treatment, it should be done with the most scrupulous care, so as to avoid reflecting on the previous management.

5.—When a Practitioner is called to a patient already under the care of another medical man, he should not interfere, unless in case of decided emergency, but should request a consultation with the latter. Should a consultation be declined by the patient, the Practitioner last called in will be justified in taking charge of the case—a communication to that effect having been made to the former attendant, and his fees paid.

6.—A consultant has no claim to be regarded as a regular attendant on the patient, and his attendance ceases after each consultation, unless otherwise arranged. The patient, therefore, or the Practitioner, is quite at liberty to call in another consultant, without the cognizance of the former, provided no appointment then exist; but in this, as in all other cases, remembering the position in which the consultant is placed, it becomes the duty of the ordinary attendant to see that the *honorarium* be not neglected.

SECTION V.

ON THE ADJUDICATION OF DISPUTES.

Whenever such cases unfortunately occur, and cannot be immediately terminated, they should be referred to the arbitration of the Council, which shall act as a COURT MEDICAL, with the distinct understanding that neither the subject-matter of such differences, nor the adjudication thereupon, shall be made public—as publicity in a case of this nature may be personally injurious to the parties concerned, and can hardly fail to bring discredit on the profession.

MEDICAL FEES

The following Tariff has been adopted by the Ulster Medical Society, and is intended to indicate the minimum of remuneration to which any Practitioner is entitled, whatever be his professional rank, or the extent of his practice. It is expected to be especially valuable for the guidance of junior Practitioners, and as a reference in disputed charges. Those Members of the Profession whose extensive practices make their time specially valuable are not supposed to be guided by these fees. In the following table patients are divided into three Classes, the basis of division being the rent of their residences.

RENTAL.

CLASS I.	£10—£25.
II.	£25—£50.
III.	£50—£100.
IV.	is "Above Class III"

TABLE OF FEES

	CLASS			
	I.	II.	III.	IV.
Single Visit , in ordinary course inside the Borough,	2s. 6d.	5s.	10s. 6d.	21s.
Special Visit , That is, on an urgent message, or when the visit has been requested after the practitioner has commenced his daily rounds.		A visit and half.		
Night Visit , that is, from 11 P.M. till 7 A.M.		Two visits.		
Seaside Visits , according to time and distance,				
Detention of more than half an hour at patient's desire or from urgency of case,	2s. 6d.	5s.	10s.	
Advice at Practitioner's Residence,		Same as visit.		
Letters of Advice ,		Same as visit.		
Attendance on Servants , If employer be responsible,	2s. 6d.	5s.	10s. 6d.	
If Servants pay for themselves,		Charge according to Class I. or II.		
Visit or Advice , of ordinary attendant with a consultant,		Two visits.		
Consultant's Fee ,		Not less than 21s., unless with the consent of the Practitioner previously in attendance.		
More than one Patient in a House, If head of family be responsible,		Half visit for each additional patient.		
If not,		Full charge.		
Simple Certificate ,		One visit.		
Lunacy Certificate ,		10s. 6d-42s.		
Certificate of Death , if Person insured, to be paid by persons interested in policy,		21s.		
Ordinary Midwifery Case (attendance beyond nine days to be charged for extra),	21s.	21s-63s.	42s-105s.	
Below Class I,		10s. 6d.		
Difficult or Protracted Labours,		An extra charge.		
Midwifery Consultant ,		Same for as first attendant.		
Vaccination by regular attendant,		By number of visits.		
Vaccination by other than the regular attendant,		One and a half the visits.		

Ulster Medical Society
Session 1879–1880
President Robert Foster Dill

LIST OF MEMBERS, JANUARY, 1880

WITH THE DATES OF THEIR JOINING THE SOCIETY.

- 1877—Anderson, R. J., M.A., M.D., M.Ch. (Q.U.I.)
1836—Andrews, Prof. T., M.D. Edin., L.R.C.S.Ed., F.R.S.
1872—Aickin, W., M.D. (Q.U.I.). M.R.C.S.E., L.A.H.D.
- 1868—Ball, T., L.R.C.P.Ed., L.A.H.D.
1868—Beck, F. E., M.R.C.P.Ed., L.R.C.S.Ed., L.A.H.D.
1843—Beck, J. W., M.D. Glas., M.Ch., L.A.H.D.
1868—Browne, J. W., B.A., M.D. (Q.U.I.), M.R.C.S.E.
1842—Browne, S., M.R.C.S.E., L.K.&Q.C.P.I.
- 1866—Cantrell, T. J., L.A.H.D.
1878—Clarke, James, M.D., M.Ch. (Q.U.I.)
1877—Clements, R., M.D., L.R.C.S.Ed.
1875—Coates, S. B., L.R.C.P.&S.Ed.
1856—Cuming, Prof. J., M.A., M.D. (Q.U.I.),
F.K.&Q.C.P.I.
1872—Core, W. S., M.D. (Q.U.I.), L.R.C.S.Ed.
- 1875—Dempsey, A., M.D. (Q.U.I.), L.R.C.S.I.
1841—Dill, Professor R. F., M.D. Glas., M.R.C.S.E.
1846—Drennan, J. S., M.D. Dub., L.R.C.S.I.
1875—Esler, R., M.D., M.Ch. (Q.U.I.)
- 1867—Fagan, J., F.R.C.S.I., L.K.&Q.C.P.I.
1862—Ferguson, H. S., M.R.C.S.E., M.D. Glas.
- 1843—Gordon, Professor A., M.D. Edin., L.R.C.S.Ed.
1877—Graham, J. M.D., M.Ch. (Q.U.I.)
1862—Gribbin, E. D., L.F.P.&S.Glas., L.A.H.D.,

**RULES OF THE
ULSTER MEDICAL SOCIETY**

I.—*Name and Objects.* The Society shall be called “The Ulster Medical Society,” whose object shall be to afford its members increased facilities of consulting the best medical works and periodicals by means of the library; of deriving mutual instruction on medical subjects, by means of its discussions and its Pathological Museum; and, as a collective body, protecting the interests of the Medical Profession.

II.—*Members.* The Society shall consist of Ordinary Members, Resident, and Honorary Members.

III.—*Qualifications.* The qualifications of all candidates proposed as members of this Society shall be laid on the table previous to balloting, with the exception of those whose names appear in the “Medical Register.”

IV.—*Election.* A Candidate for membership shall be proposed by two members at one meeting of the Society, and balloted for at the next, one black bean in five to exclude; and prior to ballot, his subscription for the current year shall be paid; if excluded, the money to be returned.

V.—*Life Members.* That when a Resident Member shall have subscribed for a period of 20 years without intermission to the Belfast Medical Society alone, or to the Belfast Medical Society in the first instance, and afterwards to the Ulster Medical Society, or to the Ulster Medical Society alone, he shall become a life member.

VI.—*Subscription.* The subscription shall be One Guinea, and payable in advance. The Society's year shall commence on the 1st November.

VII.—*Honorary Members.* Honorary Members shall be elected only at the stated Annual Meeting; the names of Candidates to be entered on the minutes at least one month previously, and proposed by four members. When elected, they shall be free to all the privileges of membership, except share in the property, without subscription, and in the ballot for Honorary Members one black bean in 10 shall exclude.

VIII.—*Rejected Candidates.* No person who has been rejected shall be proposed again within six months.

IX.—*Inability to Ballot.* That no member can ballot for a person proposed to be a member, if he has not paid his subscription for the current year.

X.—*Officers.* The officers of the Society shall consist of a President, two Vice-Presidents, a Secretary, two Librarians, a Treasurer, and a Pathological Secretary, and a Council of Six Members, all to be elected annually by a majority of votes, and after expiration of office eligible for re-election. The outgoing President to be *ex-officio* Member of Council.

XI.—*Annual Meeting.* The Society shall be specially summoned to meet on the first Tuesday in May, to transact the business of the Annual Meeting, which shall embrace the following subjects:—1. The Report of the Council. 2. The Report of the Auditors. 3. The Election of the New Office-Bearers. 4. The transaction of such other business as may come before the Meeting.

XII.—*Duties of Office-Bearers and Council.* The duties of the Office-Bearers and Council shall be to make all the necessary preparations for the meetings, to examine the contributions of members, and select for reading such as may be eligible; to report, by the aid of Sub-Committees, upon any morbid specimens which may be forwarded by members, or examination of which may be specially requested by a vote of the Society; to conduct the financial and ordinary business of the Society; to make bye-laws and other regulations not provided for in the stated laws of the Society; to report at the Annual Meeting upon all the proceedings of the session, and draw up the Annual Transactions.

XIII.—*Duties of the Secretary.* The Secretary shall keep a record of minutes, enter the cases and notices received, or remarks furnished, in their respective books, and summon and attend all meetings of the Council and Society.

XIV.—*Duties of the treasurer.* The Treasurer shall keep an account of all receipts and disbursements, and furnish his financial statement at the close of the year, and whenever required by a vote of the Society.

XV.—*Meetings.* THE ULSTER MEDICAL SOCIETY shall meet at their rooms on every Tuesday Evening, at Eight p.m., from November till May; then the First Tuesday in every month during the remainder of the Session.

XVI.—*Business of the Meetings.* The ordinary sittings

shall be limited to one hour, but may be extended at the discretion of the President; five members to form a quorum. On the first Tuesday of each month any business may be introduced without notice having been previously given. In the event of a division on any subject, the chairman shall have, in addition to his ordinary vote, a casting one in case of equality. The following shall be the order of proceeding:—

a. The chair to be taken by the President; if he is absent, by one of the Vice-Presidents—if possible, in rotation.

b. Announcements from the Council.

c. The proposal of candidates and election of new members.

d. The following, in such order as the Council may direct:—

1. The Exhibition of or Patients Morbid Specimens.

2. The results of Microscopical and Chemical Examination.

3. The Reading of Cases or Papers on Professional Subjects.

4. Notices of Clinical Facts, and Summaries of Medical Statistics.

5. The Exhibition of New Instruments and Medicines.

6. Papers on New Modes of Treatment.

7. Debates on Doubtful Points in Medical Practice.

XVII.—*Non-Payment of Subscriptions.* A member whose subscription remains due for one year shall be considered as having withdrawn himself from the Society, and forfeited all his privileges and property therein, having been noticed by the Secretaries one month previously. Such persons shall be again eligible by ballot in the ordinary way, on having paid all arrears for the year in default.

XVIII.—*Expulsion of Members.* Members may be expelled for non-professional conduct, by a vote of the Society, provided that such vote be carried by three-fourths of a meeting of at least twelve members, and that due notice of the intention to take such a vote, with grounds of the charge, be given to each member eight clear days before meeting.

XIX.—*The Property of the Society.* The property of the Society shall not be disposed of for the benefit of the Members, nor alienated from the use of the Profession, without the unanimous consent of the Society given at a special meeting summoned for that purpose, and called a month previously.

XX.—*Visitors.* Medical Students shall be admissible as visitors to the meetings of the Society. Any Medical Practitioner may be introduced to the meetings by a member.

XXI.—*Fundamental Law.* That every proposition for the enactment of any new law, or for the repeal or alteration of an old law, must be confirmed at the

meeting subsequent to that at which it was passed, previous to its becoming the law of the Society.

XXII.—*Privileges of Life Members.* That nothing in the foregoing rules shall be construed in any way to interfere with the rights and privileges, heretofore enjoyed, or hereafter to be enjoyed by the Life Members of the BELFAST MEDICAL SOCIETY, or ULSTER MEDICAL SOCIETY.

LIBRARY RULES

I.—That a member of the Society be appointed as Hon. Librarian, who, with an Assistant-Librarian, shall be responsible for the state of the Library.

II.—The Library shall be for the use of the members of the ULSTER MEDICAL SOCIETY only.

III.—No member to have more than two volumes out of the Library at one time, and no book to be kept longer than two weeks without being returned, but a member may borrow the same book for another similar period, provided no application has been made for it in the meantime.

IV.—Any member who loses or injures a book shall be bound to replace the work, or pay such fine as the Council shall think expedient to impose.

V.—The Weekly Journals to be placed on the Library table one week, and the Monthly Journals for one month, during which period they are not to be removed from the Library.

VI.—No Journal, either bound or unbound, to be removed, except through the Librarians.

VII.—Every Work, before admission, must be entered on the proposal book, and the price stated, fourteen days before the meeting at which it is to be proposed.

VIII.—That all Books shall be called in during the first week in October. Any member failing to comply with this rule shall be subject to a fine of five shillings.

IX.—That the Library shall be closed for the month of October annually, and shall then be examined by a Committee of the Council, who shall report to the meeting in November on its condition.

X. That in case any member desires the use of the Library for the purpose of consulting a work, he may do so by arrangement with the Librarian, on giving twenty-four hours' notice.

W. S. Core, M.D.,
Abbotsford Place,
Hon. Librarian.

Session 1879-80

The Fourth Meeting of the society was held upon Tuesday January 13th 1880

Present, Professor Dill President in the chair, Drs. Fagan, Harkin, Clements, Dempsey, Withers, Esler, Kevin, Anderson, McKeown, Workman, Whitla, Wales, Snr., Wales, Jnr., and Mackenzie.

Dr. Esler read a paper upon "Victoria as a health resort".

Paper:¹ Mr. PRESIDENT—There is no fact, I think, better established in the present day in connexion with the practice of medicine than that of the promptitude with which patients act in the matter of change of climate on the advice of their physician. The hand-books on medicine profess to give directions on this topic, and special treatises are published setting forth the claims of various health resorts, and from time to time articles appear in the journals giving the individual experience of members of the profession, and we constantly hear of our merchants and gentry going for a trip down the Mediterranean or up the Rhine, or wintering at Algiers, Cannes, or Mentone, because they have been ordered to do so by their doctor.

It has come within my own knowledge during the few years I have been resident in Belfast that even the Antipodes are not considered too far off for either a trip or a more extended residence for those threatened with pulmonary disease, and I have been consulted frequently, not only on the point of health, but on that of climate, business, profession, and general prospects, regarding that part of the colonies where for eight years I was resident. The information I have given to my patients I purpose in a short paper to now lay before you, and I propose to do so under three heads:—First, the patients who should go; second, the route by which they should go; third, the place to which they are going—and in the treatment of the subject I shall reverse the order, and take the last head first.

I might have made my subject Australasia, which term includes with the Australian colonies the Islands of New Zealand and Tasmania, but as my personal experience is limited to the colony of Victoria I shall ask your attention more particularly to it. Its position on the globe is on the thirty-fourth degree of latitude and between the one hundred and fortieth and one hundred and fiftieth longitude. In extent it measures three hundred miles from its northern boundary to the sea, and five hundred and sixty miles from east to west. Its area is nearly that of Great Britain. Of all the provinces on the island continent it is the most populous, most prosperous, and most wealthy, and yet its entire population is only about three-quarters of a million, the one-third of whom reside in the metropolis, Melbourne, and its suburbs. It is a new country. Its founder landed in 1836, and only for its gold fields it might not for ages have attracted the notice of men in these northern climes. It is of less importance to send a patient to any health resort as a temporary residence than as a place of permanent abode. In the former case they are seldom disappointed, in consequence of the charm of variety, while in the latter there are various considerations to be borne in mind, such as agriculture, commerce, man-

¹ [Dublin Journal of Medical Science, 1880, v69, p255.]

ufactures, educational advantages, and the openings and prospects for the rising generation; but to none of these subjects can we give consideration in this paper. The questions we must discuss are—climate, health, and longevity, and the effects of the climate on consumptive patients or others suffering from chest affections. The climate of Victoria is acknowledged to be one of the finest in the world; the temperature is moderate. It is true the range of temperature is great—between freezing point in winter and a hundred and twelve degrees in summer there is a great contrast, but these are extremes; seldom does the thermometer fall below 45°, and as seldom does it rise above 80°. The mean temperature of the hottest months is 66° and of the coldest 48°; frost and snow may be found on the highest mountain ranges in winter, but through the colony generally when ice forms during the night it melts with the rising sun. Hot winds prevail during the summer months, and this is certainly the most trying time, and the time of most uncomfortable experience to the colonist. “A brickfielder” which transfers some tons of dust or sand from one end of a town to the other end cannot be contemplated with composure, much less with delight. Yet the wheels of commerce do not stand still on this account—the trader bargains, the farmer cuts his crop, the traveller speeds on his way, and the physician on his rounds, much the same as at other times. These hot winds last, as a rule, only about three days at a time, and are followed by a deliciously cooling southern breeze or a refreshing shower, which seems to set nature right again. The seasons are different from home—there is the wet and the dry season; the former—May, June, and July—is more like our April showers than the British idea of a rainy season. Yet there are times of heavy rainfall and blustering, windy weather, when the creeks are flooded and the canvas tents on a digger’s rush are suddenly transferred by a cyclone from the gully in which they stand over the adjoining hill-top. The most usual months for floods, which are occasionally destructive, are September and October, when the rain falls in thunder-plumps. Bush fires are not uncommon in December and January, and occasionally miles of the country may be seen in a blaze of light, carrying destruction in its track. These are some, and, I think, the principal disadvantages of the climate; while, on the other hand, the positive enjoyment of spring and summer is very great. A cloudless sky; a summer heat not too great to interfere with duty or pleasure; the atmosphere light, dry, and genial, imparting comfort to the body and hilarity to the mind; the air scented with the rich aroma of the wattle bush; and the gum-tree tinted with the rich plumage of the noisy paroquet, making the bush one vast aviary, imparts to the traveller a sense of comfort and delight which gives mere existence a charm of which dwellers in humid and colder climates can form no conception. An old colonist says:—“There are days when, with good health,

the surroundings must make one happy—days on which there are brilliant floods of sunlight and warmth—the heat modified and pleasant; the atmosphere pure and dry; the breeze soothing and refreshing; the sky softly blue, or ever changing with thin cloud flocculi; hill and dale clothed with spring verdure; the earth and air teeming with joyous life. On such a day the pulse of life beats joyously, and the soul that is not chained by earthly care or bodily infirmity may enter into Nature’s great calm, and revel in an ecstasy of delight, saying with Longfellow—

It is enough for me
Not to be doing, but to be,
Through every fibre of my brain,
Through every nerve, through every vein,
I feel the electric thrill—the touch
Of life that seems almost too much.

With such a climate we may look for a healthy population, and in this we are not disappointed—there is everywhere the appearance of cheerfulness, cleanliness, activity and health. One exception may be referred to—from the habits of the early settlers in camping out at night and sleeping under no thicker roof than that of calico, one is not surprised to find rheumatic affections of the joints rather prevalent; but with more comfortable edifices and a less exposed life it is not likely that this state of things will be repeated. Epidemics such as visit Europe have been hitherto unknown, and the colonial fever of the first settlers has almost disappeared. The country is yet too young to ascertain the longevity of its inhabitants, but the death-rate presents a very favourable contrast with Britain, being 11 as compared with 23. Accidents and the race for riches, often ending in disappointment and untimely death, have greatly added to the mortality; but in these respects every year is bringing about a better state of things.

Now, coming to the main question—“Is the Australian climate likely to be favourable to the health and well-being of phthisical patients?” I unhesitatingly answer, Yes. There you have the conditions most requisite for a comfortable existence—a dry, warm, mild climate, light, bracing atmosphere, and a range and variety of temperature in the various colonies which will enable one to make choice of every conceivable variety in a few days; for, while I have spoken of Victoria as somewhat medium and typical, there is the more southern territory of South Australia, or the more northern colonies of New South Wales and Queensland; and for colder climes, there is New Zealand, or the Island of Tasmania, which is spoken of as the garden of the earth.

Having decided upon sending our patient to Australia, a not unimportant point will be, secondly, the route by which they should go. For comfort and enjoyment, and where time is no great object, there is no doubt that a first-class sailing ship, such as Wigram’s or Green’s, of London, affords a rest and quietude not to

be realised in a steamer; but, as a set-off, there are the calms of the tropics, and the cold of southern latitudes experienced in bearing down to catch the trade winds, which are anything but pleasant to a delicate chest; and, from personal observation, I should say that the voyage is generally too protracted for an invalid; yet we know that a long sea voyage is one of the conditions made essential by the most experienced medical men. The magnificent ocean steamers now plying by way of the Cape of Good Hope, or through the Suez Canal, afford a pleasant run of some fifty days, while for those who want more variety, and greater change, the route viâ New York, California, and Yokohama is available; but, on the whole, I would recommend either an emigrant or invalid to go by steamer, as being quick, safe, and moderately cheap. The best time of year to arrive there is about February or March, just after the excessive heat of the summer is over, which would necessitate leaving here two months earlier by steamer, and three months by ship.

It is usually young unmarried men who are sent to Melbourne or Sidney for their health, and I am convinced, from experience, that grave mistakes are made in not sending them further. To remain in a city in preference to going up the bush, or on to a station, is leaving more than half the work undone. In Warnambool, Belfast, or the Wimmera districts, or on the Murray River, the life is so different, and, I will say, so suitable to an invalid, that the contrast between Melbourne and a sheep station is nearly as great as between London and Melbourne. For a young man with bad health, bad habits, and a plethora of English sovereigns, a colonial town is about the worst place I know. We must remember that bad habits formed at home are not likely to improve amongst strangers with all restraints removed, and the continual temptation of fast colonial life. Man cannot fly from himself. A change of scene makes no difference in personal character; a colony can work no change in human nature; cannot prevent drunkenness coming to want; cannot inspire the day-dreamer with decision; cannot give force to the heart that quails; cannot force on those whose lives run backward; but I believe it can, and often does, arrest the development of tubercle if the patient puts himself into the conditions favourable to that end.

And now for our last point—the patients who should go. It is no uncommon thing for a passenger in quest of health to die in sight of land, and not a few have only landed to lay their bones on a foreign shore. These were sent months, or it may be years, too late. The only hope is in the early, I would say the very early, stage of tubercle. I have met men doing their full share of this world's work who told me that if they had remained at home they would have been in their graves many years before. If any good is to be accomplished, it is by sending tubercular subjects while the disease is in the incipient stage, and, to my mind, it is cruel in the extremest

degree to separate a patient from friends and home at a time when the Garden of Eden itself could not be expected to afford relief, much less to add to the patient's life. Most of the deaths from phthisis which occur in the colonies are those sent out from England, and yet the death-rate from this disease is 12 in Victoria as against 22 in England, and 14 from other diseases of the respiratory system as against 36 in England. The death-rate is much less comparatively for the country than the towns.

In Melbourne, for instance, with one-third the population of the colony, more than half of all the deaths from phthisis occur. I have been speaking hitherto of individuals, but I think a stronger case might be made out in favour of families emigrating where there is a phthisical taint, and, in place of standing by, and seeing one after another fall under the certain shaft of death's arrow, I consider it the duty of medical men to recommend families with capital, energy, youth, and a love of life to emigrate to a more salubrious clime than that in which their birth has cast their lot, so that they might not only prolong their days, but enjoy life while they do live, and assist in building up that Greater Britain of the South, which is destined yet to play an important part in the councils of the empires or republics of the future.

DR. HARKIN said he was sure if Victoria was nearer to us there would as many take advantage of it as a health resort as now go to Egypt. He contrasted it with the climate of Cannes, and thought the great disadvantage was its difficulty of access.

Dr. WITHERS asked particulars about the dryness of the colonial soil, and was told by Dr. Esler it was very dry—indeed rather too dry for the prosperity of the sheep-breeders.

DR. WALES said the subject had engaged his attention for a long time. While he thought that the sooner the patient was sent away the better, still he could not join in the wholesale condemnation of sending away at a later stage. He could recall very many cases, during his long experience, of men whom he sent away with cavities and full evidence of loss of lung substance. He detailed several cases, in some of which the patients went out almost against his commands, being seemingly too far advanced for a shadow of hope for a cure, and these in many cases turned out strong, healthy men, living still in the colonies, and leading active and laborious lives. He gave the particulars of two telling cases, in both of which there were cavities, and decided cures resulted. From what he had seen he concluded it was a very serious thing to say it was too late to send away a patient.

DR. M'KEOWN would not be disposed to go either as far as Dr. Esler or Dr. Wales. Anyone acquainted with the history of the families of Belfast could recall scores of cases where the sons of the wealthy were sent off at the very earliest period of the disease, and their pro-

gress downwards was as rapid as that of those who stayed at home. He paid a very warm compliment to the labours of Dr. MacCormac upon the fresh-air treatment of phthisis, and expressed himself as doubtful about the climateric treatment of phthisis, except in so far as climate admitted of free exercise in the open air. He thought much depended on the temperament of the patient. If fond of travel, not home-sick, not afraid to die, then the probabilities are that travel and residence at various health resorts would likely be useful. If, on the contrary, despondent, the patient would probably be much better at home.

PROFESSOR DILL, in thanking Dr. Esler for his paper, drew the attention of the Society to the law of fashion in the treatment of disease. He referred to a recent article in Blackwood, and lamented the great difference of opinion upon various medical subjects, and no department showed this more thoroughly than the question of phthisis. He gave a detailed account of the new Alpine resort for consumptives, and contrasted the extraordinary discrepancy of opinions upon the climateric treatment of phthisis. He quoted from Dr. Bennet (Mentone), and, upon the whole, he agreed with the remarks of Dr. M'Keown. His experience absolutely verified what Dr. M'Keown had stated. He detailed cases illustrative of this—cases which beautifully counterpoised those so ably put by Dr. Wales, and he concluded by saying he thought, as in disease so in health, “there was no place like home.”

Dr. Workman thought Dr. Esler had hardly given the Society sufficient information to decide where to send patients. A doctor in Victoria sending a patient to Britain, would like to know something of the differences of climate between the north of Scotland and the south of England, and between those places and Ireland, so Dr. Workman thought there must be great varieties of climate in Victoria. He would like, also, to have heard Victoria compared with the adjacent countries as to climate and its effect upon consumptive patients.

Dr. Fagan read a paper upon the treatment of nævus with cases and showed a patient.

Paper:¹ CASE I.—The child that has been shown to you this evening was the subject of a cellulose-cutaneous nævus of the upper lip, extending nearly its whole length in the vertical direction and about half an inch in its transverse measurement. She was brought to me some time back for treatment.

The first method I tried was the subcutaneous ligature. This did not succeed in destroying the growth. I then tried setons with very little better result; it remained stationary for a time, and seemed as if it were going to shrink. However, it soon began to enlarge again; and the mother being most anxious that it should be removed, I proposed taking it away by the

knife. This I did as follows:—I passed two straight needles, armed with a double-wire suture, under the base of the tumour, at right angles to the long axis, and lying parallel to each other. A hare-lip pin was next passed under its base, in the line of its long axis. They were all made to enter the sound skin about a quarter of an inch outside the margin of the tumour, and were passed deeply, so as to be felt in contact with the mucous lining of the lip. The needles and pin being left in situ, I threw a soft cotton thread round their exposed extremities; and while an assistant pressed the blood out of the tumour, I gradually tightened the encircling ligature, and then tied it, leaving the tumour, that was isolated by the pins, quite bloodless. I next carefully dissected out the tumour, keeping my knife in the sound skin about two lines outside its margin, and deep enough to nearly expose the needles. I next pushed the needles through, and brought the edges of the wound together by the twisted-wire suture. The hare-lip pin was withdrawn, and the encircling ligature dropped off. A pad of dry lint was placed on the wound, and strips of plaster brought over it, from cheek to cheek, to keep it in position.

There was scarcely a drop of blood lost in the operation. For some reason or other the mother did not bring the child back to me for eight or ten days, and during that time the dressing was not removed. I found the parts in a very dirty state—the sutures had ulcerated through, and there was a granulating sore about a line and a half wide in the course of the wound. This healed up in a few days. It is now about six weeks since I operated; there is not a trace of the diseased structure, and the slight scar following the operation will, I believe, be scarcely perceptible in the course of time.

CASE II.—The next case occurred to a child six months old, the tumour being of the same character as the one already described. It was seated on the centre of the cheek, and was nearly the size of a shilling. This I treated as follows:—I passed two hare-lip pins under its base, at right angles to one another, and threw a ligature round them, tying it tightly, thus completely strangulating the tumour.

I did not see the case for six or seven weeks after this, as the child lived some considerable distance in the country. The mother stated that in about a week the strangulated mass dropped off, leaving an ulcerated surface which was healed in about another week. For some short time before she called on me she noticed that when the child cried the place where the sore was became very red and somewhat swollen. When I saw it it had the appearance as if there was going to be a recurrence of muscular growth. Having protected the part around the cicatrix, I freely applied to it with a glass-brush a solution of sodium ethylate in pure alcohol (3ij. of the former to ziiij. of the latter). In a fortnight she called on me again, when I applied the solution a second time, and as I found it very much improved

¹ [Dublin Journal of Medical Science, 1881, v71, p80.]

after the first application, I told her she might not call again if there was no appearance of the redness returning. I have not seen her since, so I suppose it has kept well.

CASE III.—The third case is one in which the tumour involved half the lower lip, the angle of the mouth, and the mucous membrane covering the gums on that side. This I treated by seton as follows:—I got a large darning-needle armed with a very thick woollen thread. I passed this through the tumour, round its margin, a few lines from the healthy skin, after the manner of darning a stocking.

I passed another seton through its centre in the same way. I then passed two or three through the thickness of the lip, and tied all the ends together and cut them off short. The setons were moved every day, and after a little, when free suppuration was established, and the threads became quite loose, I removed them and repeated the same process in fresh parts of the tumour. I may mention that I insisted that the parts should be kept very clean, by constant washing with linen rags saturated with a strong solution of chlorate of potassium. After the removal of the second set of setons the tumour was very much reduced in size, and what was a soft, fluctuating mass had now a feeling of consolidation. I have not seen the child for the past two months, and if it is not already cured, I feel certain a few more similar applications of the seton will make it all right.

There are few subjects in surgery that present a greater variety in their treatment than *nævus*. There are advocates for the knife, the ligature, injections, caustics, cautery, electrolysis, vaccination, seton, and scarification, and the modifications of each of these methods are too numerous to mention. I have given you in a very unfinished way the notes of a few cases that occurred lately in my practice.

A few points in the treatment I may now briefly consider. In the first case I used the subcutaneous ligature ineffectually. I have used the subcutaneous ligature a great many times, and the conclusion I have come to regarding it is this—that it scarcely ever, if ever, accomplishes the end it is meant for—that is, the cutting off of the blood-supply to the tumour and the subsequent strangulation of it. It partakes, to my mind, more of the character of a seton, that for a few hours modifies the vascular supply, and if any good should follow its application, it is due, I believe, more to its action as a seton than a ligature.

The ligature, to be effectual, must occlude all channels by which blood can get to the tumour, and this can only be effectually done by including in it all the surrounding tissue, as I practised in the second case I have described.

The method of removing *nævus* by the knife has been practised by a great many surgeons—the objection to it being the danger likely to arise from hæmorrhage.

The bloodless method I have described is a modification of that practised by Seale and Buchanan and recommended by Davy. It is, to my mind, a very simple and effectual way of getting rid of the deformity with the least amount of suffering and in the shortest time, and one not at all likely to be followed by a return of the disease.

I mentioned in the report of my second case that there was a tendency to return of the disease in the cicatrix, and that it was cured by the application of the “sodium ethylate.” We are indebted to Dr. Richardson for the introduction of this powerful caustic, which will, I believe, take the place of all the others that have been used in the treatment of this affection. It has been found very successful by those who have used it in the treatment of small *nævi*, and many large ones that resisted other modes short of excision. My own experience of it is limited to this particular case, and would not warrant me in drawing any general conclusions.

In large venous *nævi* involving tissue to the amount described in Case III., the seton is, I believe, the safest and best means of treatment. Its use in the manner I have described is, I think, the surest way of obliterating the tumour. It acts in a twofold way—its zigzag course obstructing the circulation to a certain degree, while its presence, causing inflammation and suppuration in the tumour, leads to its consolidation.

DR. HARKIN thought that the operations as performed by Dr. Fagan were successful, but in cases like these he found it impossible to lay down any fixed rule, as every case had to be treated upon its merits.

DR. DEMPSEY pointed out in one of the patients the great resemblance between the scar and that seen in hare-lip, and accounted for this by the direction in which the suture was introduced.

DR. M'KEOWN dissented from Dr. Fagan's practice of sending a patient home until he had seen the final effects of his own operation. He showed many possible ways in which the treatment might be entirely useless for want of a proper adjustment at the proper moment long after the operation. Hence he did not approve of the subcutaneous ligature. He often thought that a surgeon's responsibility commenced after the operation was finished.

Dr. Fagan showed for Dr. John Moore a diseased os calcis.

Paper:¹ MR. FAGAN showed (for Dr. J. Moore) a diseased foot, removed for affection of the os calcis, which he believed was of a malignant nature. It had been gouged out some six months before, and returned with a sprouting, quickly-growing, vascular, myeloid tumour, springing from the os calcis.

R. F. Dill, President

¹ [Dublin Journal of Medical Science, 1880, v69, p260.]

Fifth Meeting January 27th

Present, Professor Dill, Drs. Wheeler, Dempsey, Withers, Mackenzie, O'Neill, Wales Snr., Browne, Esler, Workman, Whitla, Kevin, McKee, Rea, Wales Jr., and several students.

Dr. J. W. Browne exhibited a series of beautiful pathological specimens.

Paper:¹ DR. J. W. BROWNE showed a spongy exostosis which he removed from the unguis phalanx of the great toe of a healthy man who had suffered from it for two years the most distressing agony.

He exhibited a diseased larynx removed after death from a patient upon whom he had performed the operation of tracheotomy. He did not believe that the ulceration was syphilitic or tubercular. There was extensive congestion of one lung and a clot in the pulmonary artery.

He exhibited, also, a bladder from a patient which he tapped per rectum. The case was a very interesting one. The patient was a subject of the hæmorrhagic diathesis. There had been a narrow stricture of the urethra, and before he came under Dr. Browne's care an extensive false passage had been made, tunnelling through the prostate on the right side and entering the bladder; from this opening blood was oozing, but on account of the high pressure within, owing to the distended bladder, the bleeding was prevented, and when he tapped for complete retention this pressure was removed, and the consequence was the bladder filled with large clots of blood. He detailed how he attempted to get rid of these. He injected pepsine and dilute muriatic acid with a view of digesting and breaking up the clots, as recommended by Dr. Foot, of the Meath Hospital. The man sank from uræmic poisoning. A very interesting and unusual point in the case was, as the specimen showed, the remarkable malposition of the ureter—one opened in the middle line at the apex of the trigone. His incision, as they would see, just perforated the bladder in the right spot. He could not say how or by whom the false passage was formed.

He next showed a cyst, semi-solid, which had been removed from a patient; and he gave the following history:—The woman had been tapped twice outside hospital, and the fluid collected rapidly. Finally she consented to have it removed; and he made the usual incision upon Sunday last, and found such universal adhesions and such thorough continuity of tissue as he had never seen before.

He related all the difficulties as they presented themselves, and how he met them. The cyst which he showed was from the interior of the large one. He removed it to gain room, after taking away all the cyst wall possible and the fluid. He concluded the operation, which was performed under the spray, by putting in the usual sutures and a glass drainage tube designed by

Keith; and he here stated that this latter appliance he never would use again, as in removing the dressing next day he found that the glass flange had broken off, though fortunately the glass did not slip inside the abdomen. The patient did well for nearly twenty-four hours, when she suddenly commenced to sink, and died very soon, apparently from shock.

DR. BROWNE next showed a beautiful specimen of compound comminuted fracture of the forearm, extending through the elbow, and showing the T-shaped fracture as described by the late Mr. Adams of Dublin. The limb required instant removal.

DR. WHITLA had examined the specimen of diseased larynx, and he quite agreed with Dr. Browne about its origin; and he was firmly convinced of the fact omitted in nearly all the text books—that true chronic inflammation of the larynx could and does often occur, ending in ulceration, and having neither syphilitic nor tubercular origin.

He described the character of the ulceration met with in ordinary chronic bronchitis of long standing causing death, and he believed it was precisely the same state of matters in the larynx. He could recall, in his short experience, three cases where neither a tubercular nor a syphilitic nor a cancerous origin existed. He had tapped the ovarian patient outside hospital, and seen her tapped in the hospital, and he had examined the inner cyst then, and failed to get from it any fluid by inserting the trocar further in. It was, however, evident what it was through the relaxed abdominal walls.

DR. WHEELER commented upon the interest of the specimens exhibited by Dr. Browne. He thought Dr. Browne could not possibly have done anything else than operate in the ovarian case. If a man only selected such cases as must succeed, and avoided all doubtful ones, his power for good was very limited.

DR. WITHERS detailed a case where two exploratory operations had been made and the patient recovered, the capital operation being abandoned.

DR. KEVIN detailed a very interesting case bearing upon the bladder specimen, where the organ was tapped three times in twenty-four hours.

DR. O'NEILL spoke of the careful and dexterous way in which he witnessed the ovariectomy performed by Dr. Browne. The adhesions could not have been previously foreseen.

PROFESSOR DILL commented upon the care required in the selection of cases of ovarian disease before operation, strongly recommending the exploratory tapping before operating as the best guide to diagnosis. He pointed out the great advantage in operating at the Throne Hospital and not in the Royal.

Dr. Whitla exhibited two specimens of calculi removed by lithotripsy.

¹ [Dublin Journal of Medical Science, 1880, v69, p564.]

Paper:¹ The first was from a girl of six years, who presented herself at the Ulster Hospital for complete incontinence of urine of two years' duration. On an examination under chloroform, he found a large stone; and though his intention at the time was only to make a diagnosis, he was tempted to operate on the spot. The urethra, which just admitted a probe, was dilated by a pair of fine dressing forceps, and the stone easily caught, but extraction was impossible owing to its size and shape, without destruction of the soft parts. It was oblong, and lay with the great diameter across the bladder. A stout pair of necrosis forceps were introduced, the stone caught in the middle of its length and broken in two. Each piece was found to be too large for removal, and a further application of the forceps crushed them into the fragments which they saw in the specimen before the Society. These were removed with some trouble, and by their size an idea of the dilatibility of the urethra might be learned. One was as large as a bean. The passage was dilated during the extraction so much that he easily introduced his little finger and explored the bladder thoroughly. He expected that a good time would be required before the canal would resume its tone again, but he was astonished to find that the little patient was able to keep her urine for two and a half hours after the operation, and continued to improve rapidly, leaving hospital in about a week perfectly well. The stone was phosphatic, and weighed nearly half an ounce, and before removal seemed to entirely fill the bladder, which had contracted round it, the urine as it was carried by the ureters dribbling continually away. More than a year had passed and she was now in perfect health, and had no inconvenience whatever.

The history in connexion with the second specimen was interesting. A stout healthy gentleman, about thirty-eight years of age, had suffered from severe pain of a paroxysmal character in the left hypochondriac region, which was supposed to be of splenic origin by his medical attendant. He lived in England. He had several attacks of this kind, the last being about eighteen months since. About two months ago he received a letter from this patient describing most accurately the symptoms from which he was then suffering—symptoms evidently caused by stone. He wrote to him to that effect, and advised him to travel at once to London and see an hospital surgeon there; but forty-eight hours afterwards the patient walked into his study after crossing the Channel. He passed the small sound, which the members would see was a slight modification of Sir Henry Thompson's curve, and detected a small stone, which the patient affirmed gave an audible note. Upon the second day after this, Dr. Wheeler having administered chloroform, he passed Weiss's smallest size lithotrite, caught the stone and crushed it three times,

the operation lasting about a minute and a half. No irritation of any kind followed.

As Dr. Workman, who watched the case, remarked, there was not a trace of blood to be seen in the urine after this crushing. He bore the chloroform so badly that upon the next operation forty-eight hours afterwards, assisted by Dr. O'Neil, he passed in the lithotrite and only caught two small fragments which he reduced to powder, and washed the bladder out with Clover's apparatus. From thence the convalescence was very rapid. He was put afterwards under ether, and very carefully examined by himself and others, and subsequently by Professor Gordon, and no trace of stone was found.

The fragments, they would observe, were all sharp and angular, and composed of oxalate of lime. The stone was very minute; all that could be collected amounted to not quite 22 grains, which he was certain was at least two-thirds of its entire weight. Though so small, probably not larger than a pea, its presence caused most excruciating agony for more than a year, preventing to some extent the patient, who was the owner of some coal mines, from pursuing his business. From the shape of the fragments they would see that the particles of the stone were united at angles to each other, giving it an almost spinous structure. Pain very much subsided after the first sitting, and entirely disappeared after the second. Upon the eighth day the patient walked several miles with complete freedom, which had not been his experience for more than a year before. Dr. Whitla then referred at some length to Bigelow's operation, which, he thought, marked a new era in the treatment of stone. He was satisfied that a few angular fragments in the bladder were far more dangerous than the prolonged contact of polished steel instruments in careful hands. He showed the great advantages that arise from using a small sound with a sharp curve, and believed that he could not have detected the small stone with the large old-fashioned sound, while he thought he could not pass in the small one without striking it. He exhibited a small metal bougie which he had made for the treatment of fine strictures, its novelty being its peculiar curve, which was hardly perceptible, it being almost straight. Over a year has now elapsed (while going to press), and the patient has never once had a return of his old pain.

DR. WHEELER said he had the opportunity of witnessing the operation which was followed by so successful a wind-up, and he must say that he thought it would have been painless without the chloroform. He was surprised that the patient felt so relieved after the sitting, as he stated to him he felt no inconvenience whatever. He spoke about the difference between the treatment of stone now and what it was in his student days, when lithotripsy was almost unknown.

Dr. J. W. BROWNE said he decidedly was in favour of a clean cut for stone. He detailed several cases upon

¹ [Dublin Journal of Medical Science, 1881, v71, p83.]

which he had operated, and he could recall one in which he was now certain had he performed lithotomy he would have had a very different result. Both the cases before the Society he thought very successful.

DR. O'NEILL described the steps of the operation, as he had seen the patient, and he now understood what he had read in Sir Henry Thompson's book about detecting a stone not bigger than a pea and crushing it at once. The operation was performed without any difficulty, and what convinced him of the great advantage of lithotrity was that he saw that there was not a trace of blood on the instrument or afterwards, and he could not see how in such a case coming before any surgeon again there could be a word spoken in favour of cutting.

PROFESSOR DILL, in thanking Dr. Whitla for his specimens, commented at length about the different operations for stone, and expressing himself confident that every year the cutting operation would become rarer and rarer, as diagnosis became easier, because stones would now be detected when they were small and crushed without danger. Both the cases were to him of great interest. He had not seen Bigelow's operation, but he could see it was based upon rational grounds.

Dr. O'Neill's paper upon Colles' fracture was postponed.

R. F. Dill, President

Session 1879–80

Sixth Meeting of the Society was held upon Tuesday 10th February '80.

Present, Professor Dill, Professor Gordon, Drs. Wales Snr. and Jnr, Dr. Esler, O'Neill, J. W. Browne, Withers, Kevin, McHarry, Workman, Fagan, Whitla, McKee, McConnell, and about 40 students.

Dr. Fagan exhibited a patient with a deformity from Colles' fracture produced 23 years ago.

He also showed a patient upon whom he performed double osteotomy, and a new splint for disease of the wrist joint.

Paper:¹ MR. FAGAN exhibited a splint he contrived for extension of the wrist in acute diseases of that joint, a description and woodcut of which can be seen in the Report of the Transactions of the British Medical Association at the Cork Meeting in 1879.

Dr. O'Neill read a paper upon Colles' fracture and Professor Gordon opened the debate upon it.

Paper:² FRACTURES at the lower end of the radius are of great practical importance, from their frequency and the evil consequences arising from the common methods of treatment still recommended in most surgical works. There are two chief forms.

The first form is usually called Colles' Fracture, so named from having been accurately described by Dr.

Colles, Dublin, in The Edinburgh Medical and Surgical Journal for 1814, Vol X, pp. 182–186, and is usually caused by a fall on the palm of the hand, with a simultaneous forcible extension backwards of the hand.

The second form is produced by a fall on the back of the hand with the wrist flexed. The latter form is very rare, so I shall confine my remarks to the first variety.

Causes.—It is usually caused by falling on the palm of the hand, with the wrist violently extended; the anterior common ligaments and flexor tendons being forcibly stretched, act on the anterior border of the carpal surface of the radius at right angles to its long axis, forcing it backwards so that the radius breaks almost transversely, or with a variable degree of obliquity from before backwards and upwards.

Signs and Symptoms.—1. Swelling over the posterior surface of the wrist, extending upwards on the forearm for about 1½ inches, as the natural hollow over the wrist-joint behind is obliterated, and seems to be transferred to 1 inch or 1½ inches upwards on the forearm. This is caused by the lower end of the lower fragment being displaced backwards with the carpus and metacarpus, and the tonicity of the muscles displaces the lower fragment outwards.

This deformity disappears when moderate extension is made, and returns immediately when the extending force is withdrawn, as formerly described by Dr. Colles himself.

2. Swelling at the lower end of the radius in front, beginning close above the wrist joint and extending upwards from 1 to 2 inches on the anterior surface, the natural concavity of the radius at this part being replaced by a prominence.

3. The lower end of the styloid process of the radius is directed towards the base of the metacarpal bone of the index finger, instead of being in a line with the metacarpal bone of the thumb, as in the normal condition.

4. Acute pain along the seat of fracture in front and behind and over the lower end of the ulna. The pain over the ulna is longest of being recovered from.

5. Inability to pronate or supinate the hand because of the severe pain caused by the attempt to do it; therefore the patient keeps the hand midway between pronation and supination, at the same time supporting the forearm across the chest with the sound hand.

6. By firmly grasping the lower end of the radius close to the carpal border by one hand, and at a point two or three inches upwards on the radius by the other hand, and making moderate extension with backward and forward movement, distinct mobility with occasional crepitus are felt between these points. This sign is conclusive evidence that a fracture exists.

The line of fracture in this accident is described as transverse from before backwards by Smith ("On Fractures in the vicinity of Joints," page 165, Dublin, 1847), Holmes ("Principles and Practice of Surgery," page 247,

¹ [Dublin Journal of Medical Science, 1881, v71, p83.]

² [Dublin Journal of Medical Science, 1880, v69, p566.]

2nd edition), and Packard (*American Journal of Medical Science*, January, 1879, page 124); but Professor Gordon, Belfast, who has carefully studied this subject, states “that of 27 specimens of this fracture in the Belfast Queen’s College Museum 19 are oblique from before backwards and upwards, and 8 are directly transverse” (“On Fractures of lower end of Radius,” page 4; Gordon, 1875).

In the recent forms of this fracture, produced artificially, the line of fracture is oblique from before backwards and upwards, and from within outwards and upwards, extending in front $\frac{1}{4}$ of an inch above the carpal border, and behind from $\frac{3}{8}$ to $1\frac{3}{4}$ of an inch above the carpal border. The lower end of the upper fragment is found to be convex from before backwards and upwards, and from within outwards and upwards, and the upper end of the lower fragment is concave in these directions.

Mons. Voillemier (“Archives Générales de Médecine,” Mars, 1842) maintains that all fractures of the lower end of the radius (that is, within an inch of its carpal surface) are examples of impacted fracture, and considers that impaction of the upper into the lower fragment prevents crepitus from being detected in this form of fracture.

Nélaton agrees with him in this view (“Éléments de Pathologie Chirurgicale,” tome I., page 742). Smith (“On Fractures in the vicinity of Joints,” pages 159, 160) denies that impaction does occur, and remarks that “until the result of the examination of recent specimens can be adduced in support of the theory of impaction I shall be inclined to believe that the impaction is only apparent, and that the compact tissue of the shaft is not found enveloped in bone, from its having penetrated the lower fragment at the time of the occurrence of the injury, but because it becomes subsequently incased in osseous matter during the process by which the bony union of the fracture is accomplished.”

Professor Gordon, in 1875, and his pupils since then, produced this fracture artificially, in the dissecting rooms of the Queen’s College, Belfast, by forcibly extending the hand; and now the more important varieties of this fracture have been represented by artificial ones.

On careful dissection of these fractures produced artificially the line of fracture begins, as a rule, from $\frac{1}{4}$ of an inch above the carpal border of the radius in front, and passes from within outwards and upwards, and from before backwards and upwards, for about an inch; the upper fragment being convex and the lower concave in these directions—viz., from within outwards and upwards, and from before backwards and upwards. In none of these specimens was impaction observed—in fact, it will be easily understood that no impaction can take place in this form of fracture, as its direction is oblique in the directions before mentioned, and because the force which produces this accident acts at right

angles to the longitudinal axis of the radius, and rotates the lower fragment upwards and backwards on the lower end of the upper fragment.

Treatment.—Extend the wrist-joint, then apply Gordon’s splint—by placing the bevelled portion of the anterior part of the splint a little above the lower end of the upper fragment—to fix it; now flex the wrist to an angle of 45° , and apply the posterior part of the splint to press forwards, and retain the lower fragment in that position.

The splints must be well padded with spongiopiline, flannel, tow, or other soft material. Place a thick elongated pad of tow (about 1 inch x $\frac{1}{2}$ x $\frac{1}{2}$) against the outer border of the carpus longitudinally, pass a narrow strap through the ulnar part of the splint and over this pad, so as to press the carpus inwards towards the ulna. Fasten the splints by two more straps—one over the splints close to the lower end, and the other over the splints close to the upper end. Secure all by a bandage extending from the fingers to the elbow. Should severe inflammatory swelling of the hand occur during the first twenty-four hours, I remove the posterior part of the splint and readjust the padding. This may be repeated once weekly to watch the progress of the case, and any displacement of the fragments should it arise. In patients under fourteen years of age three weeks will be sufficient time to allow the splints to remain on; above fourteen years four or five weeks will be required. After removing the splints entirely envelope the hand and forearm in cotton wool, and lightly bandage for two or three weeks. See that the fingers are kept frequently moved from the second week after the accident to prevent prolonged stiffness, which may occur if this point is not attended to.

I have treated more than 150 cases in the Belfast Royal Hospital by applying Gordon’s splint in the method above described, and, with few exceptions, have found that the patients soon regained the perfect use of the forearm and hand. Several patients, especially those over fifty years of age, suffered from pain of a rheumatic character along the line of fracture in cold weather, but this was easily remedied by applying cotton wool and a bandage for a longer time after the splint was removed than in younger patients. The accompanying diagram represents Gordon’s splint accurately applied for the treatment of Colles’ fracture.

PROFESSOR GORDON, after the paper was read, made the following observations:—The first thing to be determined is—What is Colles’ fracture? I would define it as

the usual fracture of the lower end of the radius, caused by falling on the palm of the hand, and very rarely extending above an inch from its lower end. In such cases, if the splint be properly applied, the lower end of the radius will be so perfectly restored that it will be difficult to say after five or six weeks which radius was fractured. If the radius be broken from an inch and a quarter to an inch and a half above the lower end, then both fragments are usually displaced inwards, diminishing the interosseous space. In such cases the splint will fail in correcting the displacements inwards, especially of the upper fragments, as it is held in this position by the extensor muscles of the thumb; but I do not know of any more efficient splint for the treatment of this variety of fracture. Indeed the question has often forced itself upon me as to the necessity of limitation of Colles' fracture, so as to give it a precise meaning, and draw the distinction between fractures of the lower end of the shaft of the radius and Colles' fracture. If the fracture be in the lower inch of the radius, and the term Colles' fracture be restricted to that inch, then the treatment of it will be found most satisfactory by my splint; but if the fracture be a little higher up, then a slight diminution of the interosseous space and transverse breadth of the forearm will occur, which neither the radial splint nor any other mode of treatment with which I am acquainted will correct. As to the age at which it occurs, I have seen it in persons from five to twenty-three years of age, and from twenty-five to thirty-five years it becomes very rare; and after fifty years, when senile atrophy begins to manifest itself, it becomes very frequent—so that even the slightest force may produce it. As to the palmar swelling, it is mainly inflammatory, and is caused by the lower end of the upper fragment starting forwards and wounding the soft parts in front. By pressing the upper fragment backwards and the lower forwards, the apposition becomes perfect, all stimulus to inflammatory action is removed, and in many cases there is no swelling of the fingers nor tingling sensation, which was, before the introduction of my splint, considered a necessary accompaniment of Colles' fracture.

And as to the doctrine of impaction in this accident, all I can say on the subject is this—that I have seen and carefully examined several hundreds of the specimens of the artificial fracture, and in none, either produced by myself or by others, was there the slightest appearance of impaction—as the force exerted on the anterior border of the carpal surface, as stated by Dr. O'Neill, drives the lower fragment backwards, whilst the lower end of the upper fragment, being in projectile force by the weight of the body, is forced forwards against and into the flexor muscles, and, therefore, I regard impaction almost as a mechanical impossibility; but as regards that form of fracture produced by falling on the back of the wrist, as referred to in the paper just read, I regard it as a truly impacted fracture, of which I have

two admirable specimens in the Queen's College Museum.

Dr. JOHN WALES did not think that the successful treatment of Colles' fracture was by any means confined to the use of the "Gordon splint."

DR. WALES (senior) thought there could be little doubt as to the great value of the Gordon splint in the treatment of Colles' fracture, as defined by Professor Gordon, if correctly applied. We see, however, even amongst well-informed surgeons, considerable difference in its mode of application. For example, it is frequently applied so as to make lateral pressure on the upper fragment of the radius, near the seat of the fracture, the result of which must be to aid the pronators in diminishing the interosseous space—thus creating a deformity which he had frequently seen as a sequence of this fracture. He thought, therefore, that the principles enunciated by Professor Gordon, rather than his splints, commend themselves most—for attention to the former will enable any intelligent surgeon to construct, out of materials at hand, an appliance which will produce satisfactory results, where such can be produced, by the Gordon splint. But this is not always the case, even with the latter. A suitable pad on the anterior aspect of the upper fragment, immediately above, but not on, the line of fracture; a pad on the end and posterior aspect of the lower fragment and carpus, secured by two plain splints—leaving the hand well flexed and the fingers free, to prevent stiffness from adhesions—would, he believed, meet all requirements in a simple manner.

DR. FAGAN approved of Nélaton's method of treatment instead of Professor Gordon's. He had not much experience of the practical application of the splints, and though he spoke more theoretically than practically, he had given the matter some thought, and he must say he failed entirely to see the intention of the bevelled portion of the splint; nor could he see why the accident could not be as well treated by a piece of straight and flat wood properly padded. While he could see no use in this part of the splint, he thought that its convexity would be sure to produce some lessening of the interosseous space. From an anatomical study of the subject there was no necessity for it. He could not see how it would keep the radius and ulna from approaching each other, as was contended by those who advocated its use.

Dr. A. M'CONNELL said he had considerable experience of Gordon's splint, and used it in all cases to which it was applicable. Its advantages are very evident in cases which have been neglected from two to three weeks. It is easily applied, retains its position without trouble, and effectually corrects any deformity. The splint is a great boon to the practical surgeon, and we owe a deep debt of gratitude to Dr. Gordon for his invention.

Dr. WHITLA said he would refer to a point which was overlooked in the discussion—viz., the latest period

in which one was justified in treating a fracture by the Gordon splint. He had applied it in one case where the accident was of four weeks' standing, in another of three and a half, and in several where the bones had been more than a fortnight fractured—all with great benefit. He thought there could hardly be a limit put to the time, as the splint, properly applied, would restore the natural condition of the parts so perfectly that, even if firm osseous union had taken place, great good would follow its use, as the alteration in the direction of the articular surfaces would be prevented even after a very long time. As regarded the use of the bevelled portion of the splint, he thought that there was hardly room for a difference of opinion when anyone looked at the beautiful natural antero-posterior curve in the perfect bone which he held in his hand. In case of fracture this concavity in the radius was almost always changed into a convexity. The inventor of the splint had early seen and recognised the vast importance of restoring this concavity, and he made the bevelled portion of his splint the keystone of his arch, and with consummate skill succeeded with the simplest contrivance to remedy a deformity that had previously baffled every surgeon. He had used, or seen the splints used in, he believed, over 200 cases, and in no instance where it was applied properly, had he seen any but highly satisfactory results follow; and he believed he was perfectly correct in saying that in nine cases out of ten no proof of fracture could now be detected upon the most critical examination.

Dr. WORKMAN understood Dr. Fagan to speak of the bevelled portion of Dr. Gordon's radial splint as being used to make and keep up a lateral separation between the radius and ulna. Dr. Workman had always been taught by Dr. Gordon that the bevelled portion was not intended for, nor was it capable of performing, such a duty, but was intended to keep the upper fragment of the radius in a plane posterior to that of the ulna; and he knew of no plan of padding which would be at all so effectual as the radial splint. Dr. Workman considered it unnecessary, as a rule, to place the little pad which Dr. O'Neill recommended on the outer side of the carpus, under the carpal strap, but wished to call attention to the advantage of placing a very thick, small pad on the back of the carpus. A pad so placed would keep the carpus with the lower fragment of the radius well forward, and this carpal strap, passing from the back splint to the prominent base of the metacarpal bone of the thumb, would exercise no injurious pressure on the veins. From his experience he had found it better, as a rule, not to keep the splint on for more than about four weeks, for in several cases where the splints had been left on for about six weeks, on removing them he found that, although there was no deformity, the fingers and wrist were very stiff—apparently from the hand being kept in one position for such a length of time—so much so that it was many weeks before the hand had per-

fectly resumed its functions. Dr. Workman thought that spongiopiline or felt was the best substance for padding the splint, but in hospital he was in the habit of using tow, only on account of its cheapness, and had found it to work admirably.

The PRESIDENT said:—I believe I am warranted in the statement, and I think I reflect the minds of the members, when I say that a more important practical and useful paper has not been brought before the Society for a long time than this one, to which we have been listening with so much attention, by Dr. O'Neill, on Colles' fracture and the Gordon splint, and which has been so ably supplemented, and minutely and clearly demonstrated, by Professor Gordon. I have had a lengthened and ample experience in the use of this splint, and I may say that its value cannot be exaggerated, neither can we bestow too much praise upon its admirable adaptation to the wrist and forearm, the great comfort experienced by the patient, and the very satisfactory results which have been found to follow from its proper application. I am free to state that, before this instrument was designed and came into use, I always experienced a want or a deficiency in the treatment of those cases of Colles' fracture which came under my care, as there was a greater or lesser degree of deformity following in each case; but I have invariably found the results to be most satisfactory since I began the use of it. When I first saw and carefully examined for myself the Gordon splint, it at once commended itself to my mind and judgment as a mechanical contrivance which was admirably suited to the object for which it was designed; and I cannot imagine anyone possessed of a mechanical mind or genius but who must see and acknowledge its undoubted merits.

And yet, with all this, I regret to say that, from what I have both seen and heard, there are those in the profession, far and near, who, as has been stated, require still to be educated into the use and proper application of this instrument. To prove this I shall offer you one or two instances. The first is that of a lady who came to me from a little distance. She had her arm in a sling, had on it the Gordon splint, and she was suffering much pain. I found, upon examination, she had received a Colles' fracture, and that the splint was actually applied upside down. No wonder, indeed, that she suffered so much. I need not say I altered the splint, and adjusted it so as to afford her much ease, and the case did well. The next case was told me by one of our young graduates (a Belfast student) who, while visiting a metropolitan school, dropped into a lecture-hall. The subject of clinique was Colles' fracture, and, after exhibiting the Gordon splint, the lecturer proceeded to show how it should be applied. The young graduate could scarcely preserve his countenance when he saw it being applied in the wrong way, or upside down. He took the liberty of introducing himself afterwards to the lecturer, and correcting the error which to a Belfast man

was a palpable blunder. As a few of the members are not agreed upon what constitutes a proper padding between the splint and the wrist and forearm, I may say that I have often applied it without any padding whatever, and when it is made to fit in size and shape, I have seen it to suit the purpose admirably. But before using it in this way I have found it necessary to round off the anterior sharp edge. This I would venture to suggest to Professor Gordon as an improvement under any circumstances. Allow me to conclude by saying that, if, as I assume it to be a test of genius to supply an admittedly great want by producing an original and very appropriate mechanical contrivance, and which has been furnished to us in the invention of this admirable work—then, I submit, to Professor Gordon, the author of this very valuable surgical appliance, the “Gordon splint,” must be accorded the honour of being an inventive genius.

J. W. Browne, Vice-President

Session 1879–80

Seventh Meeting 2nd March 1880

Present, Professor Dill in the chair, Dr. Harkin, Dr. McKeown, Dr. J. W. Browne, John Moore, Dr. McHarry, Dr. Withers, Dr. Esler, Dr. Dempsey, Dr. McKee, Dr. Workman, and Dr. Whitla

Dr. Harkin Ex-President read a paper upon chlorate of potash.

Paper:¹ It is generally known, I believe, to the members of the Ulster Medical Society, that I have for many years been an earnest advocate of the use of chlorate of potassium in the prevention and treatment of disease, and that I have already on two occasions submitted the results of my experience to the consideration of the profession at large. I have written, as it were, two monographs—each one devoted to a special phase in the curative action of the remedy. My first paper, read before the Society, and published in *The Dublin Quarterly Journal of Medical Science* for November, 1861, was entitled “The Use of Chlorate of Potash in the Treatment of Consumption and Scrofula.”² The second, upon “Chlorate of Potash in the Hæmorrhagic Diathesis,” was communicated to the British Medical Association, at its meeting in Cork in August, 1879, and detailed at length my experience of its curative agency in cases of epistaxis, hæmophilia, purpura hæmorrhagica, hæmaturia, menorrhagia, hæmatemesis, hæmoptysis, and hæmorrhage from the rectum.

My intention at present is to demonstrate the beneficial effects of the remedy in another department of medicine. My great difficulty, however, is to make a selection, as there is not, in reality, a single class in the nomenclature of disease that I might not refer to in proof of the salutary influence of this drug. When I

state, as the result of my observation extended over a great many years, that this salt exercises a most potent influence on all maladies dependent upon defective nutrition, secretion, excretion, æration, and molecular metamorphosis—that it possesses the power of developing vital force in weakened constitutions, of retarding the degeneration of the tissues, and of frequently controlling the too rapid advance of senility, due to climacteric conditions—the difficulty of selection will be at once apparent.

Before proceeding further, I may be permitted to refer to its *modus operandi* its dose and mode of administration. My theory is that, being principally composed of two elements indispensable to the formation of healthy blood—viz., oxygen and potassium, its administration, especially where one or other of these substances is deficient, tends to improve and elevate the condition of the circulating fluid, upon which the health of every organ of the body depends. When a solution of chlorate of potassium is taken into the stomach, a portion—as is the rule with iodide and nitrate of potassium—is carried off by the kidneys; another portion passes by diffusion into the liquor sanguinis, the textures, the blood globules, and white corpuscles; a third may be supposed to part with three equivalents of oxygen in the blood, leaving behind chloride of potassium, which may be detected in the urine as well as in the blood, of which it is an important element. After its continued use the patient experiences an increase of appetite—of *nervo-muscular* force; all the bodily functions are performed with greater ease, the colour improves, and the flesh producing power is manifestly augmented, as evidenced by increased weight, the character of the blood itself being altered by an addition to its fibrin and plastic qualities. When required for internal use, I generally order it as a saturated solution, say one ounce of the salt to twenty of water, of which for adults one ounce three times daily either before or after food. Most useful by itself, yet its efficacy in arresting disease, in chlorotic or hæmorrhagic diatheses, may be greatly enhanced by the addition of iron in one of its many forms, the most convenient being the *tr. ferri perchlor.*

With the permanganate of potassium it forms a most excellent gargle and mixture in sore throats with diphtheritic exudation, and for the healing of ulcers; it also forms a good base for many pectoral mixtures. As to the tolerance of the drug, I know not of any remedy so generally well borne. I have prescribed it for patients of all ages and conditions with wonderful success and advantage, and, while I can safely state that thousands have been benefited by its use, I can count upon my fingers the number that it has disagreed with. I have met a few cases in which it produced unpleasant symptoms, and some with peculiar idiosyncrasies, in whom it had to be dispensed with altogether. Like other salts of potassium—the acetate and the nitrate—it occasionally

¹ [*Dublin Journal of Medical Science*, 1880, v69, p398.]

² [See page 255.]

acts, though in a less degree, as a diuretic, but this condition is far removed from nephritis—a disease which Jacobi asserts to be frequently produced by its use. In all my experience I remember but one case that at all approached this condition—it was that of a young German lady, a subject of phthisis, living in Holywood, who, while taking the chlorate, certainly suffered most painfully for a number of hours from strangury, but who recovered by the ordinary means of stupes, hot baths, &c. Dr. Cutter, a very able American physician, told me of a case that occurred to him while crossing in a transatlantic steamer, that recovered with difficulty after taking only ten grains of the salt. As a contrast to this, I may relate the case of a strong young man who, having been supplied with a gargle containing an ounce of the salt, through mistake drank the whole at a draught, and did not experience the least inconvenience in consequence. Whilst, therefore, I do not give any credence to the exaggerated statements which have lately appeared in the medical journals, I do not think that the prescription of this remedy should pass, like cod-liver oil, out of the control of the profession, and become a merely popular medicine, but that it should be given with caution, although without reserve, under medical supervision.

Perhaps among its many valuable qualities none is more remarkable than the rapidity with which its application as a lotion heals up the injuries due to burns and scalds, so often by ordinary treatment both tedious and troublesome to cure. It is quite surprising how soon the healing process commences after the application of the lotion, and the raw surface is covered by the formation of new skin. This rapid improvement takes place not only when vesication is extensive, and the cutis more or less destroyed, but also in the more severe cases, where not alone the cutis but the subcutaneous tissue is destroyed, and even when ulceration is present after the separation of the eschars—the condition which makes the treatment of burns and scalds so troublesome to hospital surgeons, and the wards allocated to their treatment so often foul and offensive.

After a few applications of the lotion a zone of new skin appears proceeding from the circumference, day by day speedily narrowing the denuded surface, till at last the wound is healed. The chlorate of potassium lotion appears to possess the power of favouring the secretion of fibrin in peculiarly plastic condition, and of hastening the formation of new tissues, and thus completing the reparatory process, and the healing of sores. I shall try to illustrate my position by an example. About twelve months since a member of the Royal Irish Constabulary received a scald upon his right hand, producing a painful blister, and he applied to me for advice. My friend, Dr. J. W. Browne, happened to see him at this visit and subsequently. I directed the man to puncture the blister, and remove the cuticle by a poultice, and then to apply a lotion composed of five grains

of chlorate of potassium and one ounce of water, every four hours; twenty-four hours alter its application he returned, already the healing process had commenced, and a border of newly-formed cuticle, one half inch in breadth, presented itself. Next day a further narrowing took place, and so on, till at the end of five days the cure was complete.

Another case, on a larger scale, occurred in the Male Industrial School, then located in Donegall-street, about seven years since—that of a little boy who stumbled when lifting a pot of boiling broth, and received the contents down his back, which blistered him from the neck to the nates. On visiting him I directed the back to be poulticed for twenty-four hours with bread and water, and after the removal of the detached cuticle the surface of the scald to be dressed with lint, and the lotion of the same strength as above to be frequently renewed, and a mixture of the saturated solution to be given in half-ounce doses three times daily. This case comported itself like the former one, the cure was most rapid, and the lad was able in seven days to put on his clothes and resume his ordinary avocations.

CASE III.—I shall only refer to a third case—that of a brewer's man, who was scalded by the overflowing of boiling wort, and blistered on both thighs. In his case the greater part of the blistered surface healed within a week, but some ulcers, with troublesome granulations, required the lotion to be doubled in strength before finally yielding.

An important item is to apply the lotion three or four times daily, to add the permanganate if any offensive discharge arises, and to maintain the strength of the patient by the administration internally of large doses of the salt.

Closely allied to the condition of a scald or burn is that of a sloughing ulcer, due to the application of a blister in enfeebled constitutions. This ailment is usually treated with the *lotio nigra*; the chlorate lotion will be found to be more rapidly successful in giving a healthy cast to the surface of the wound. I shall relate a remarkable case in proof of its power:—

CASE IV.—About ten years ago I was in attendance upon three children of a family living in Murray's-terrace, suffering from scarlatina with diphtheritic exudation and high fever. The two elder patients had required blisters on the throat, which healed without any trouble; not so with the third, a girl of six years, for, twenty-four hours after its removal, the blistered surface assumed an unhealthy appearance; it then began to slough, and soon the healthy surrounding skin became similarly affected, and the slough extended from the chin to the sternum, and from the ears to the collar bones; but the slough took another direction, and after the skin and fascia of the neck it destroyed the *platysma myoides*. And the cellular tissue on the left side, leaving the external jugular quite isolated and the sternocleido-mastoid muscle as well defined as on the

dissecting table. The external jugular being quite occluded I snipped it off with a pair of scissors. The disease still proceeded, and the external carotid was laid bare, and was observed pulsating vigorously at the bottom of the wound. Matters now looked serious, and I thought it right to ask Dr. Murney to give me the benefit of his valuable counsel. He advised the application of my favourite remedy, chlorate of potassium, ten grains to the ounce as a lotion; the result was, that in twenty-four hours one-half of the right side of the neck was healed, and in two days more it was completely cicatrised, the healing process proceeding from the circumference to the centre. The left side, with the deep-seated slough, also healed completely within five days, leaving the child unable to laugh without distortion of the features from the destruction of the skin muscle on one side and the absence of antagonism. However, after about a year, some principle of compensation seemed to be established, and the deformity disappeared altogether.

In the treatment of caries of the vertebra of the neck, by the injection of a solution of the salt I have had on two occasions the greatest advantage; and in cases of strumous abscesses and sinuses treated by injection the cure is generally very rapid—of course in every case the constitutional requirements being attended to by the internal administration of the salt.

Case V.—About twelve years since I was called to see a patient in Lagan village, a married woman, nursing her first child, but in a very delicate, wasted condition, due to a profuse discharge which came from her left shoulder-joint, of a scrofulous nature; there were several openings about the insertion of the deltoid muscle, and the drain was so debilitating that the patient appeared to be in an advanced stage of consumption. I prescribed the internal use of the chlorate of potassium, and injected the sinuses daily, with a weak solution of the salt. Her health immediately began to improve, and in three weeks the discharge had ceased altogether, the arm resuming its ordinary functions. I have seen the patient lately; she carries on the business of a shop in a stirring part of the town.

CASE VI.—Mammary Abscess and Sinuses.—In July, 1868, a lady called on me for advice. She had been suffering from an abscess in the breast for three months. Her baby was five months old, and she had never nursed. She was much exhausted, and in a very nervous condition. On examination I found that the right breast was painful and inflamed, and that there was a purulent discharge proceeding from live openings, the outlets of five sinuses which had subsisted from the date of the original abscess. I prescribed the mixture of the ordinary strength, and injected each of the sinuses with a solution of ten grains to the ounce. When the patient called next day already one of the orifices was closed. I then injected the four remaining; next day another had closed, and by the end of five days the last

sinus was permanently healed. The lady's health was re-established at once, and she has since given birth to three other children.

The effect of chlorate of potassium upon ulcers, simple, irritable, indolent, and rodent, is very remarkable. I might point to several cases at present under my care for ulcers in the leg and on the head, the results of wounds; but would merely state that they heal just as I have described in the case of burns. The hard and elevated edges of old ulcers give way to flattened and healthy ones, and the excavated surface of the sore is altered by the oxygenating power of the lotion and replaced by healthy granulations.

CASE VII.—I shall relate but one case, that of an intelligent, educated man, himself a doctor residing in Kilkenny, who applied to me by letter for advice in 1864, suffering from painful chronic ulcers, that had reduced him so much that he had to get a substitute for his dispensary practice. I have fortunately two of his letters remaining. I shall read them for you; they tell their own tale. In the first letter he says:—"I am now a week using the c. of potash internally as well as externally. There is a great change. The sore is healing, the integuments so unhealthy and breaking away are now pale and healthy looking, and the irritation for which I had to take morphia, as well as add it to the local application, is so much subsided as to enable me to dispense with the morphia locally, and to reduce the internal use from $1\frac{1}{2}$ grains to $\frac{3}{4}$ daily. The elevated and everted glazed edges of the sores are now flattened and dipping into the ulcer. You said it truly when you mentioned that in the chlorate of potash I should find what I'd been long seeking. How can I thank you for the benefit you are doing me? Your remedy stands upon sound therapeutic principles, and is true.—Kilkenny, 5th October, 1864."

He writes again, 30th October:—"I may say I am just healed; the sore is skinning ever so rapidly; I expect it to be entirely closed in a few days." Later on he writes:—"Though not quite healed, and this owing to my being obliged to undertake dispensary duty too soon, yet I have but two ulcers, the size each of a shilling. When I discontinue the chlorate internally I find I am obliged to resume it. It at once improves the aspect of the sore. I have since used it in leucorrhœa and in purpura, in combination with tr. mur. ferri, as you suggested, and with most beneficial results. In a case of the latter disease, a child was under other treatment for months, the first 8 oz. mixture of chlorate with iron astonished its parents, the result was so manifest."

This poor gentleman was finally cured and restored to usefulness and health, and with his case I conclude.

Dr. Meharry congratulated Dr. Harkin upon the success of his cases. In ordinary practice most men combined iron with the chlorate. He did so, but always attributed the good effects to the iron. He would watch it now with interest.

Dr. Withers wished to see its local application more extensively used. He asked for an explanation of its action. Did it act by mild astringency or by stimulation? He had seen it lately tried in the case of a large indolent sore with success after everything had failed.

Dr. Moore thought that Dr. Harkin was too sanguine in his opinion about the efficacy of the chlorate. He detailed his experiences of it in many and different diseases, thought that often it was uncertain and useless; but, upon the whole, there was no doubt that chlorate of potassium had won for itself an honourable place in *Materia Medica*. It was, unfortunately, used so often in combination with iron that there was great difficulty in coming to a conclusion about which agent did the good.

Dr. J. W. Browne said his father had used this medicine so extensively that he was known amongst the students as "Chlorate of Potash." Perhaps he inherited some of the veneration for the drug, and used it often, and more than once with marvellous success. As regards its use in mammary abscess—of which he had four severe cases last year—he injected a solution, and at the same time gave it internally, with most decided benefit. He could say the same of its use in ulcers, only he would remind anyone about to try it that a solution of more than five grains in the ounce would smart considerably.

He then detailed his treatment of burns—first he applied a poultice, and after it came off he had a solution of the salt laid upon the burns, and, in many cases, in twenty-four hours, a new growth of a quarter to a half inch of skin could be seen. He referred to a paper by Mr. Jonathan Hutchinson, and said he could fully corroborate his statements about the very decided benefit of the powdered salt in phagedenic ulceration. He then detailed some important effects which he had observed from chlorate of potassium in various diseased conditions, especially gonorrhœa, in which disease he made a mixture of the salt containing 1 drachm in 2 ozs. Two drachms of this were to be used every second hour for the first twelve hours, and always with great success.

Dr. Whitla had a good deal of experience of the use of chlorate of potassium in the two widely different classes of cases in the Children's Hospital and the Old Charitable Hospital. In the cases of children's disease he must say they simply could not do without it. How it acted he would not pretend to say, still less would he pretend to go into any chemical theory, but he was satisfied it produced very decided change of action in the secretion of most mucous membranes in unhealthy children. He had watched narrowly its action in cases of tonsillitis and pharyngitis, and though he thought it did great good, one thing he was positive about—viz., that if continued beyond the proper time it kept up and increased the congestion. This he had often demonstrated, and the moment its use was stopped the throat got immediately better. He then detailed some cases of

chronic ulcer in the aged where its use was decidedly beneficial.

Professor Dill said at this stage in the history of the profession and in the nineteenth century it was refreshing to hear a paper brought up by a man like Dr. Harkin upon a purely practical subject of such therapeutic interest. He then described the general course pursued by most consultants, nearly all of whom, in his experience, contented themselves by making out the diagnosis of the case. He referred at length to the effect in this direction of the teaching of Laennec and his disciples, many of whom laughed at the idea of treating disease with medicines. He was glad, however, to see that the tendency was now reviving of treating disease with medicines. He expatiated upon the therapeutic action of the drug and the evidences of its decomposition into the chloride and oxygen. He thought as regarded the treatment of burns that the old plan of allowing the blisters to remain without puncture was the best, and he felt he would be slow to follow out the line laid down by Dr. Browne.

Upon the subject of enlarged glands he said we required to know a good deal more than we did about the laws which governed diseased action in these peculiar organisms; how common it was to meet with enlarged glands which resisted all treatment, and which, as far as we were able to tell, differed in no way from those which disappeared as if by magic.

Dr. McKeown read a paper upon a new treatment for relaxed tympanum.

Paper:¹ I have pleasure in bringing before you the results of a somewhat large experience of a new method of treatment of relaxation of the *membrana tympani*, which I have already submitted to the notice of the profession at the meeting of the British Medical Association at Cork in August last. I am happy to say that my faith in it has not waned, that from my first application of it till the present time I have used it almost daily, and that I have the firm conviction it will take its place as one of the most important aids in the treatment of diseases of the ear.

When a claim is advanced for the introduction of a new method and a new principle in the treatment of disease, it is desirable to review the present state of knowledge. On examination of the works of the most eminent authorities in aural science we shall find that—No method of Treatment of any value has been proposed or practised for Relaxed Membrane.—Sir William Wilde, in his classical work on "Aural Surgery," writes:—"This is a cause of deafness most difficult to treat, but unless some other disease coexist with it we may generally assure the patient that his deafness will not increase. When once the membrane has been pressed for any length of time inwards it is very diffi-

¹ [Dublin Journal of Medical Science, 1880, v69, p502.]

cult to restore its position permanently. Many persons inflate the drum by holding the nose and making a forced expiration whenever they wish to hear what is said. In others we can temporarily restore the position by Eustachian catheterism, but in both the membrane returns to its former condition in a short time. I have tried the effect of exhausting the air in the external meatus by means of a syringe accurately adjusted to the outer aperture, but I have not effected any good thereby. On the contrary, I think the congestion produced by the exhaustion is rather detrimental to the organ. I have frequently afforded temporary relief by dropping with a glass tube a little nitrous ether into the meatus, and immediately stopping the external aperture either with the finger or by pressing the tragus over it. Some slight pain is instantaneously felt, followed by a boiling sensation, then a glow of heat, and a feeling, to use the patient's expression, as 'if the drum of the ear was sucked out.' It is difficult to understand how this remedy acts and assists to restore the membrane to its normal position."

Hinton, in his work on the "Questions of Aural Surgery," says:—"In milder degrees of indrawing of the membrane, when, though it can be restored to its place by inflation, and temporary improvement follows, it soon falls back again, Politzer introduced and still speaks highly of the plan of keeping up an air-tight closure of the meatus. Having well inflated the tympanum, he takes some cotton wool rolled up into a small ball with wax or ointment, and with it closes the orifice of the meatus. He thus takes off the pressure of the external air, and even turns to account the absorption of air in the meatus, making it tend to draw the membrane outwards, care being always taken to see that the Eustachian tube is free. The ball may be worn for several consecutive nights, and then omitted for the time. When the membrane is atrophied, however, this plan does not succeed. But then excision of the relaxed part, whether it be a scar or a part otherwise thinned, will sometimes be of use; or if the relaxation has advanced only to a less degree, and the membrane simply lacks the proper tension, simple incisions into the most relaxed part of the membrane help towards a restoration of the normal tension, apparently through the contraction that attends their healing. The incisions may be frequently repeated, and at short intervals; but in this climate, and with the kind of patients we usually see, I should prefer always to let fourteen days elapse." It will be observed how unsatisfactory is the testimony of this conscientious observer regarding the treatment he proposes. It looks as if he thought these means should be useful rather than that they were. He says nothing of his personal experience of Politzer's method. To cut out a piece of the membrane is not an operation easy of execution nor altogether safe, and simple incision is, in my opinion, very unlikely to increase the tension. Certainly he has not

advocated these operative measures in such a way as to lead to their adoption, and we have no data on which to form an independent judgment.

Toynbee deals with the subject, and gives details of cases in which he treated intercurrent inflammatory attacks with success, but we have not a suggestion regarding the treatment of the condition of relaxation.

I need not further quote from authorities. I may briefly state that the works of Von Troeltsch, St. John Roosa, Turnbull, Dalby, Field, and Macnaughton Jones, either pass over the subject altogether or fail to make any valuable suggestion for treatment.

Importance of the proper tension of the Membrane.—There can, I think, be no question that the membrane has at least two functions—viz., to receive vibrations for conveyance through the ossicles to the labyrinth, and to support the handle of the malleus. If the membrane in whole or in part have lost its proper tension, it is, I think, evident that the vibrations will not be conveyed with due regularity, that different vibrations succeeding each other may be confounded, and that a dulness of hearing may result from the confusion necessarily resulting. Further, if the membrane at parts be depressed so as to touch structures within the tympanic cavity, the force of the vibrations may be diverted from its proper channel. It is likewise evident that one part of the membrane may be depressed without materially interfering with the support of the handle. If the membrane be of proper tension in two or three different radial directions, the handle may be well supported, and the hearing consequently will not suffer from this cause. If, on the contrary, the whole of the anterior or posterior segment should be defective in tension, then the handle can have no longer proper support, and is likely in time to assume a faulty position, as a rule, in a direction opposite to that in which the tension is defective. When the whole membrane lacks proper tension, then the handle usually inclines inwards too much, and brings about intra-labyrinthine pressure and nervous disturbance. In some instances the handle as well as the membrane has far too great a range of motion both inwards and outwards—this being no doubt caused by insufflation and forced expiration.

Having now a notion of the functions of the membrane, we may examine with advantage—

The Clinical Characters of Relaxation of the Membrane.—I do not deem it necessary to enter upon a discussion of various diseases which may lead to this diseased condition, but shall simply observe that relaxation is usually brought about either by inflammatory processes in the membrane itself, leading to a loss of resisting power, or by long-continued pressure of the atmosphere on a drum-head exhausted during the course of Eustachian disease. Let us suppose, however, that the original cause has disappeared, and that we have simply to remedy results. The clinical characters are very characteristic, and somewhat varied. As you

would expect from the unsteady condition of the membrane, the hearing power varies quickly and remarkably. At one minute the hearing of the patient may be average, at the next quite dull. The fact is, it could scarcely be otherwise, considering that in many cases the membrane flaps in and out in a most irregular manner on every act of swallowing—indeed almost with every change of position of the head. The patient usually has either been taught, or has found out, that distension of the tympanum by forced expiration—the nose and mouth being closed—improves the hearing for the time, and he therefore resorts to this very frequently for the sake of the temporary improvement induced, but so soon as the membrane collapses he is as bad as before.

Various unpleasant subjective sensations find a ready explanation from the condition of the membrane. For example, the feeling as if the ears were plugged with wax, or some foreign substance is caused by the inward pressure of the collapsed membrane on the ossicles. The confusion of voices, of which many complain, arises, in all probability, from the vibrations not being quickly conveyed and terminated, because of the want of tension of the membrane. The sensations of opening and closing, or of something falling in the ear, are very frequently experienced by the patients, and are clearly produced by an actual physical cause—viz., the movements of the membrane. Some extraordinary noises, of which patients with this disease sometimes complain, may be located in the membrane and cavity of the tympanum, and entirely removed from the objectionable category of nervous disease. It does not require a great stretch of imagination to conceive how rattling, thundering, creaking noises arise from movements of the membrane and ossicles. A patient under my care at present says that he had a feeling as if something were knocking about in his ear when he breathed deeply, blew his nose, or shook his head. Clearly the cause was in the middle ear, and, I have little doubt, was caused by a relaxed membrane, with probably some loosening of the connexions of the ossicula. This view is borne out by the fact that the symptom disappeared on the restoration of proper tension to the membrane.

On inspection of the membrane we find the greatest variety in the appearances. Sometimes the membrane retains its normal transparency; sometimes it is opaque or somewhat thickened, in whole or in part; the membrane may be relaxed, in whole or in part; the depressed part may gradually slope into neighbouring parts, or may be separated from them by a well-defined margin. In some cases the depressed part is involuted, as it were, so as to be in part hidden beneath the surrounding membrane; or may be so pressed down upon the ossicles that the latter are clothed with the membrane.

To complete the examination of the condition of the membrane, it is necessary to inflate the drum by one of

the usual methods. In this way we may determine whether the case is one simply of relaxed membrane, or of relaxed membrane complicated with adhesions. If forcible expiration causes all the depressed parts to bulge, then it is clear the membrane is not adherent; but if by this method no change, or only slight change, is induced, then it will be necessary to use Politzer's method. I have several times remarked that forcible expiration only partially elevated a depressed membrane, and that Politzer's method completed the elevation.

It is especially important to note the relation of the handle of the malleus—viz., whether it is inclined too much inwards or outwards, backwards or forwards; whether it stands out prominently, with membrane depressed before and behind, or has given way entirely to the in-pressing membrane. In the majority of cases deviation in one or other direction will be found.

Prognosis hitherto.—At the best, as Sir William Wilde has remarked, the condition may remain stationary, but too frequently matters take an unfavourable course.

The unsteady condition of the membrane, and the consequent varying degree of in-pushing, are sources of irritation, lead to vascular and nervous disturbance, and often bring about intercurrent congestive attacks. Besides, a non-adherent relaxed membrane may become adherent, and then the case becomes greatly aggravated.

The very treatment recommended by some aurists—and frequently practised by patients to secure temporary relief—only tends to augment the loss of tension; I mean Valsalva and Politzer's methods of inflation. Distensile force frequently applied to a structure already deficient in resistance will generally still further diminish its power of resistance. But insufflation, though clearly injurious in the long run, may be required to prevent the immediate occurrence of a greater evil—viz., adhesions during an inflammatory attack. As regards distension of the tympanum, we may say that its practice may do harm, and that its omission may do still greater.

To restore Lost Tension is the Rational Treatment of Relaxed Membrane.—I trust I have now brought you with me to the point of concluding that to restore tension should be our great aim in the treatment of relaxed membrane. That this can be done now with great ease and safety admits of no doubt. At the meeting of the British Medical Association referred to, I showed that contractile collodion applied on the membrane of the tympanum adhered firmly, contracted the membrane to a greater or less extent, whilst it remained adherent, and also exerted a permanently beneficial influence on the relaxation. I am happy now to report that my anticipations regarding the permanent restoration of tension—that is to say, the cure of the condition of relaxation—have been realised.

History of the first case cured by the application of Collodion.—The patient was an unmarried woman, aged forty-one. She had been under my care from time to time for three years on account of catarrh of the drum and its results, and treated by me according to recognised methods. With the left ear she heard my voice (moderate tone) at a distance of three feet, but the hearing varied much. The noises in her ears were of the most distressing kind. At times the noise was like that of a thunderstorm, again like that of machinery, and sometimes like the blowing of a horn. The sounds of other persons' voices were greatly confused ("entangled," as she put it). Her own voice seemed to her to have a most unnatural tone. She formerly sang in church, but since she became deaf her own voice seemed to her so inharmonious that she was obliged to cease singing. At times she was quite bewildered, and she told me that she believed her noises would have put her mad, had she not been obliged to earn her bread. On examination of the membrane, I found a number of depressions between the upper part of the handle of the malleus and the posterior wall of the meatus. All these depressions became bulgings on inflation of the drum by Valsalva's method. I applied collodion freely. Her hearing was immediately improved, and continued steady. She came to hear my voice (moderate tone) at the distance of eighteen feet, and the noises in the ear ceased. The confusion of voices, and the unnatural character of her own voice, disappeared. She became able to sing as she had formerly done. The depressed part became quite flat. On July 29th (that is, about three months after the application) I thought the layer of collodion loose. I syringed, and found that the loosening was only partial, and that the layer did not come away at all readily. The hearing remained good and the depression had disappeared, probably owing to the long-continued bracing up. The membrane seemed too lax, however, and I put on another coat two days afterwards. At present the hearing is stationary, the relaxed part has its normal tension, there is not the slightest depression at any part, the membrane has become perhaps more than usually transparent, and the patient has not had a single unpleasant noise since my first application. Two applications have sufficed to bring about a permanent cure of the relaxation. No other treatment of any kind has been adopted.

Critical examination of the history of the above case.—But it may be asked was the improvement really owing to the contractile influence of collodion or to some other cause, or to several causes combined? Was the good result a mere coincidence? We know that deaf patients are usually influenced beneficially by a very dry atmosphere, injuriously by a damp one—beneficially by heat, injuriously by cold. The patency of the Eustachian tube improves the hearing, and obstruction diminishes it. Now, I desire to exclude from this case every source of error, and to show that we must con-

clude that the increased tension induced by collodion was the only cause of the improvement. The facts, then, which stand out prominently are—

1st.—That for three years the patient had been subjected to varied treatment by myself, without satisfactory results.

2nd.—That the application of collodion was followed by immediate improvement.

3rd.—That no other treatment was resorted to, either simultaneously with, or subsequently to, the local application of collodion.

4th.—That it is unreasonable to suppose that any chance circumstance of a general character had any influence, as she has been since exposed to varied temperatures, and has continued her ordinary mode of life, but still the improvement has continued throughout.

5th. That only two changes were induced by the collodion, viz.—slight increase of thickness and increase of tension, with steadying of the ossicles. We may dismiss the increase of thickness as the cause of the improvement—indeed, it could easily be excluded by experiment. There only remains, therefore, the increase of tension.

6th. That the permanent cure of the relaxation was owing to the action of the collodion, there being no other cause in operation. Besides, the previous experience of the profession pointed to the permanency of the condition when once established, and this departure from the previous invariable rule was, no doubt, owing to the agent now used for the first time.

This now brings me to the enunciation of what I may call a general law, viz.:—

That the structures of a living body, no matter how resistant they may be, expand or contract, as the case may be, under the influence of purely mechanical forces, and may continue in the new condition of expansion or contraction permanently—in other words, the structures of the body accommodate themselves to new conditions most readily. We are all quite familiar with numerous apt illustrations—as, for example, the lengthening of the ligaments and fibrous structures on distension of joints; the enormous distension of the hydrocephalic head; the increase of the capacity of the fibrous capsules of various organs; the increase in the area of the cornea and sclerotic under increased intra-ocular pressure, and the diminution under diminished intra-ocular pressure; the permanent shortening of ligaments, muscles, and tendons, in prolonged flexion of the limbs; the diminution in area of the capsules of organs on atrophy of the structures of the organ. Likewise, as the membrana tympani permanently increases in area or relaxes under the atmospheric pressure, so it shortens permanently under the long-continued contraction of collodion.

I have, perhaps, in the opinion of some, entered upon this subject too fully. I do not think so, however. I have endeavoured to avoid a mistake too common in

medicine and surgery—of hastily concluding that a certain effect was owing to a particular cause, when it might be really owing to another cause or combination of causes. I am the more particular in dealing with this question in a strictly logical way, as I desire that a method of treatment which has been so successful in my hands should be adopted by my professional brethren, not simply on my representations, but because it is rational.¹

R. F. Dill, President

Eighth Meeting 16th March 1880

Present, Professor Dill in the chair, Dr. Wales, Dr. Anderson, Dr. Workman, Dr. McKee, Dr. Withers, Dr. Esler.

Dr. Anderson read a paper on “Respiratory excitation and depression”.

Paper:² AUTOMATIC respiratory actions have their origin in the medulla and spinal cord. In the former the respiratory bundle is a cord 1 mm. in thickness, which consists of varicose nerve fibres, and is united at its origin with the nucleus of the vagus. This cord receives fibres from the glosso-pharyngeal vagus and spinal accessory, and is connected also with the hypoglossal. In the middle and lower part of the medulla the bundle divides into parallel branches, and these appear to stand in relation with the phrenic nerve. In the dorsal and upper part of the lumbar region the posterior vesicular column, which consists of ganglion cells and nerve fibres, and is most sharply and distinctly limited in the position of the lower dorsal and upper lumbar nerves, establishes a connexion between certain fibres of the posterior roots and other parts of the spinal cord of the same side.

In continuous connexion with this nucleus are scattered masses of cells in the cervical and sacral regions of the spinal cord. In the spinal cord the respiratory bundle is a longitudinal cord of fibres, which may be traced upwards to the medulla oblongata. Nerve fibres pass upwards to the higher nerve centres that establish a connexion between this and the respiratory centre.³ Thus respiratory centres exist in the medulla and spinal cord, capable not only of propagating but of reflecting stimuli. The principal respiratory centre is situated near the *calamus scriptorius*.⁴

Nerve fibres that serve for different respiratory purposes are connected with the medulla oblongata and spinal cord; motor nerves, that act on the muscles of inspiration and respiration; and sensory nerves, that transfer stimuli from distant parts to the respiratory centres, and ultimately to the muscles concerned in the

respiratory acts. The vagi are distributed to the muscular structures found in the trachea (at the extremities of the rings and between the rings),¹ bronchi, and lungs, and the same nerves contain different fibres that are destined for the mucous membrane of the air-passages.

The lung substance and certain respiratory muscles are supplied with ganglia, which confer upon them a certain degree of independent action. Kölliker² found ganglia in the lung substance—a fact that has been confirmed by other observers; and in connexion with the distribution of the right phrenic nerve Luschka³ pointed out the existence of the phrenic ganglion. The experiments of Brown-Séguard with reference to the rhythmical contractions of the diaphragm and other muscles showed that these ganglia are not without their use.⁴ The connexion that exists between the terminations of sensory nerves distributed to the air-passages and to various other parts of the body with the motor apparatus of the chest and abdomen causes the latter to respond to stimuli applied to the former, and section of nerves by which the centres are deprived of existing stimuli produces a change in the character of the respiration.

The effect of cold applied to the external surface in adults and children is an often-mentioned illustration of the effect of a stimulus applied to the peripheral extremities of sensory nerves, and irritation of the peripheral endings of the fifth and other nerves in the air-passages is sufficiently conclusive. The excitation of a sensory nerve was shown by Schiff to produce an increase in the number of respirations, provided such stimulus be moderate. If, however, the stimulus be strong, a diminution takes place, and inspiration tetanus may result.

Division of the vagi increases the depth and diminishes the number of the respirations (Fig. 1), whilst stimulation of the central cut extremity increases the number, and, if strong, will give rise to inspiration tetanus; the rhythmically active agents in expiration in this case become quiescent. The power of a reflex stimulus was found to affect the muscles of inspiration in the same order as increasing dyspnoea—viz., the diaphragm, the external intercostals, the intercartilaginous muscles, *levatores costarum*, *scaleni*, and *serratus posticus* (Traube).⁵ The agents that were rhythmically contractile before became quiescent during the stimulation.

Stimulation of the superior laryngeal nerve, if moderate, diminishes the number of the respirations; if strong, it produces expiration tetanus. Thus, in one of Rosenthal's experiments, with a moderate current (coils 200 mm. distant), the diaphragm was quiescent, the

thorax remained in the position of rest, no muscle contracted, and the thyroid cartilage moved quickly up and down.

With a stronger stimulation (coils 160 mm. distant) there was quiescence of the diaphragm, tetanic contraction of the abdominal muscles, great diminution of the thoracic cavity, and depression of the ribs.¹ The action of the superior laryngeal nerve is thus comparable to the action of the splanchnic on the intestines and the vagus on the heart, with this difference, that the centres on which these nerves act are situated in the organs themselves, whilst in the case of the former nerve the centre is situated in the medulla oblongata. (The researches of Legallois and Flourens showed that the centre for the diaphragm was situated in the medulla.) The fact that stimulation of the superior laryngeal nerve produces inhibition of the diaphragm by its action on the nervous centre in the medulla confirm the opinion of Ludwig and Weber that the two nerves above referred to produce inhibition by acting on nerve cells situated in the organs to which they are distributed.²

The connexion of the respiratory centres with the higher parts of the nervous system ensures a certain amount of controlling power. By the will the number of respirations can be increased or diminished, and the respirations are influenced by the degree of activity of the cerebrum. The effect of close attention upon respiration is an often-mentioned illustration of this fact.

Certain changes in the blood produce very marked effects upon the respiratory actions. The blood so altered may cause these changes by its action upon the respiratory centres or upon the peripheral terminations of nerves connected directly or indirectly with them.

The effect of the introduction of certain substances into the blood is well known. Atropia, for example, when given in small doses, increases the number of the respirations—in large doses it diminishes. Opium retards, and its action is distinct after section of the vagi.³

Strychnia increases the number and depth, and phenic acid causes the respirations to become, first, rapid and regular, and then rapid and feeble.⁴ The effect of morbid poisons has only to be mentioned.

An increase or diminution of oxygen in the blood gives rise to phenomena which are due to an increased or diminished stimulus to the nerve centres, which may take place as the direct effect of an increased or diminished stimulus, or indirectly by the increased or diminished oxidation of certain products in the blood.⁵ An increased amount of carbonic acid acts as a powerful

stimulus to the respiratory centre.

Dyspnœa can be produced in an animal to breathe nitrogen or carbonic acid (700 to 30CO₂). In the former the quantity of oxygen in the blood is greatly diminished, the quantity of carbonic acid being little affected; in the latter the carbonic acid is greatly increased, whilst the oxygen Pflüger found in some experiments increased.¹ Dyspnœa can be produced by opening the thoracic cavity and puncturing the lung over the surface; if oxygen or air be forced into the lung through the trachea the dyspnœa disappears, and will reappear if carbonic acid or nitrogen be substituted for the former gases (Traube). It can also be induced by fitting a stop-cork to a trachea canula and diminishing the aperture.²

The following method, adopted by Dr. von Kries and myself in our experiments in Professor Ludwig's laboratory, has this advantage, that the responses in different experiments can be easily ascertained and compared. A trachea canula was fitted to Müller's bottles;³ the dyspnœa was produced by lowering the tube in the mercury of the inspiration bottle. Some of the results are shown in the following table:—

Time	Number of respirations in five sec.	Temperature	Resistance in mm.	Duration of resistance
H. M. S.				Seconds
4 17 0	0.45	38.2	0	—
4 22 0	0.5	38.6	0	—
4 24 0	1.1	38.6	5	35
4 24 35	0.7	38.6	0	—
4 24 0	1.0	38.6	5	35
4 26 30	1.0	38.6	0	—
4 27 0	0.5	38.6	0	—
4 29 30	0.8	38.6	2	103
4 31 0	1.5	38.6	0	—
4 32 0	4.4	38.6	0	—
4 33 0	1.0	38.4	2	150
4 36 0	1.0	38.4	0	—
4 37 0	0.55	38.4	0	—
4 43 0	0.833	38.4	2	150

In another experiment, with a resistance of 0 mm. of mercury, the number of respirations was 6 per minute; with a resistance of 5 mm. the number was increased to 13.2 per minute; and with a resistance of 2 mm. the number of respirations was 10 per minute. The vagi were cut at the beginning of the experiments. Bert has made numerous experiments with reference to the effects of obstruction. They will be found in his book on Respiration.⁴

Dyspnœa and asphyxia can be produced by supplying

an animal with air or oxygen which contains ozone. The effects of a change in the condition of the oxygen inhaled have been studied by Professor Redfern, Dr. Barlow of Glasgow, Dr. Richardson, and others. Dr. Redfern made use of mice in many of his experiments. The ozone was prepared by electrolysis, and, after being purified, was passed into the chamber containing the animal. A mouse (in Experiment XI.), weighing 60 grains, was placed in the chamber containing oxygen and ozone, at 4 33 p.m.; in half a minute the eyes were closed; in a minute the head was elevated during inspiration. At 4 35 the mouse was removed, and exposed to a current of air, but no improvement took place. At 5 15 the animal is still breathing almost imperceptibly; eyes closed; can walk a few paces when disturbed. At 10 10 the animal, which has remained quiet since last report, and whose respirations have been regular (87 per minute) during the greater part of the time, is attacked now with dyspnœa. The animal died at 10 30 p.m. The right side of the heart was found gorged with blood; the left side was empty.

In order to determine whether the dyspnœa was due to closure of the glottis, an opening was made in the trachea. The animal (in Experiment XIV.) was then introduced into the chamber; in 2½ minutes the mouse fell over on its side, and in 3½ minutes died.

In Experiment VIII. the mouse commenced to inhale the ozone at 12 27; at 12 52 the mouse moved about uneasily, and rubbed its nose; at 12 58 convulsions and death. It will thus be seen that death resulted from asphyxia, the heart in this case also being gorged with venous blood. The experiments of the same observer on rabbits, frogs, insects, and worms, were attended with similar results. These experiments have been confirmed by the observations of Dr. Barlow,¹ who considers the asphyxia to be due to an alteration of the lining of the air-cells by the ozone.

In the experiments recorded above, the amount of ozone present was about the ½₂₄₀th part, the remainder being oxygen; so that oxygen, in the form of ozone, is a very powerful agent in the production of dyspnœa.

Dyspnœa produced by heat is of interest to the physician and physiologist.

If an animal is introduced into a hot-air bath, and the temperature so regulated as to produce an increase in the temperature of the animal (the temperature is determined by means of a thermometer placed in the vagina or rectum), when such an increase is sufficiently great, the respirations increase in number, and diminish in depth.

The respirations can be registered in various ways. The apparatus of Marey² and Bert³ are described in their works; many other methods are given by Cyon.⁴ A

very convenient method is the following:—A small bag connected with a glass tube is introduced into the œsophagus, and passed down to the thorax to within a short distance of the œsophageal opening of the stomach; the other end of the tube is connected with a Marey's tambour; the bag is dilated with water, introduced by means of a syringe after the bag has been passed down to the thorax.

An alteration in the capacity of the thorax causes a movement of the lever of the tambour, so that the respirations can be easily registered. Table II. gives the results of an increased temperature upon the respirations of a dog (Figs. 3 and 4).

Table II. (The temperature and the number of respirations in five seconds are given.)					
Temp.	Resps. in five seconds	Temp.	Resps. in five seconds	Temp.	Resps. in five seconds
o		o		o	
39.8	8.5	40.5	8.0	41.1	11.0
39.9	3.7	40.6	3.7	41.2	6.4
40.0	3.7	40.7	4.9	41.3	5.4

40.3	2.6	41.0	7.4	41.6	7.3

The table confirms the results of Ackermann and Goldstein.¹ A reference to the table and plate will show that two very important changes take place in the respirations—viz., an increase in frequency and a diminution in depth; and whilst the former is generally characteristic of dyspnœa, the latter is present in a different condition, to which I shall hereafter refer.

The dyspnœa so produced is referable to one of the following causes—direct stimulation of the respirations without a corresponding stimulation of the inhibitory centres, or a weakening of the latter without affecting the former. In the former case, the centre itself, the peripheral extremities of afferent nerves, or the cerebrum, are the parts to which the stimulus is applied; in the latter, the respiratory inhibitory agents are the parts affected. If the increase of temperature acts only on the inhibitory centres, then the excitor nerves would either produce apnœa by their own action, or assist artificial respiration in producing it in case complete oxygenation be sufficient for that purpose. Ackermann and Goldstein have shown, however, that apnœa cannot be produced by artificial respiration when an animal suffers from heat dyspnœa, and this although the blood contained in the veins became bright red during the experiment—hence the stimulus must be due, in part at least, to the direct or indirect stimulation of the excitor centres. That heat dyspnœa is not due to the

presence of venous blood alone, the experiments of Ackermann and Goldstein show; that it is almost entirely due to the increased temperature, our experiments seem to prove, as artificial respiration altered but little the character of the respirations.

The stimulus may be applied to the respiratory centre directly or indirectly, as already mentioned. Goldstein's experiments show that the dyspnoea is not produced by the action of the heat upon the peripheral extremities of the sensory nerves, on the peripheral extremities of the vagus, or the higher sense organs. Gold applications to the surface, cutting the vagi, and the administration of narcotics, did not affect the results. Heating the carotid in a water bath was found sufficient to produce heat dyspnoea.

The amount of air breathed during this form of dyspnoea seems to be greatly augmented. Several methods may be used in an investigation of this kind. Müller's bottles may be employed with water or mercury, or Czermak's lever¹ applied to the chest, and connected with an electromagnetic arrangement which alternately opens and shuts the inspiratory and expiratory tubes. For the determination of the gases, Regnault and Reiset's modification of Lavoisier's apparatus is the most accurate.²

The respiratory movements of an animal cease under certain circumstances, and this though the heart beats as before, and the actions of the body remain unaltered. This condition was named apnoea by Rosenthal. Hook, in 1667, opened the chest of a dog before the Royal Society, and by means of a bellows forced air into the lung, which escaped by punctures made over their surface. He found that "the eyes were all the time very bright," and the heart beating regularly; there was no respiratory movement³ (Sanderson).

Apnoea can be induced by forcing air into the lung by a series of blasts (60 or more in the minute). The air escapes from the chest after each insufflation, by an aperture in the canula. The duration of the apnoea is influenced by the duration of the artificial respiration that has preceded it.

I have frequently obtained apnoea for 15 seconds in dogs by employing artificial respiration for one minute, and apnoea for 25–30 seconds by artificial respiration of two minutes' duration. By prolonged artificial respiration, however, apnoea may be obtained for two minutes (Cyon,⁴ Pflüger⁵), or even for five minutes (Rosenthal). Ewald, by artificial respiration for half an hour in a dog, obtained apnoea for half a minute to a minute and a half. This was followed by one or two superficial inspiratory actions, which were succeeded

by a pause; after ten minutes normal respiration was established.

In considering the causes of apnoea, it is necessary to take account of the condition of the blood during the cessation of respiration, and the nature and action of the force employed. Ewald found that the oxygen in the blood was slightly increased, and the carbonic acid distinctly diminished.¹ In one of his experiments (Versuch 4, Serie II.) the arterial blood was a brighter red during apnoea than before it. Pflüger found that the amount of oxygen taken up during artificial respiration was sometimes greater and sometimes less than normal—the amount of carbonic acid given out greater. Finkler and Oertmann showed that the amount of oxygen in the blood depends on the force used—anything that diminished rapidly the circulation diminishes the oxygen—and that whilst at the beginning the amount of oxygen taken up is apparently less, and the amount of carbonic acid given out is greater, the reverse held after the cessation of the artificial respiration. They further showed that the colour of the venous blood depends on the character of the artificial respiration and the energy of the heart's action.² The respiratory centres thus lose any stimulus due to the diminution of oxygen or the increase of carbonic acid; quiescence in the active respiratory agents is the result.

It is necessary to take a glance at the effects produced in an animal by breathing pure oxygen. Several observers have directed their attention to this subject. Professor Redfern prepared pure oxygen from peroxide of manganese. The gas was purified by means of lime-water and caustic potash, and passed into a large receiver, placed over lime-water; into this receiver a jet of lime-water kept constantly playing. Two mice were introduced into the atmosphere of oxygen (Experiment XIX.), and were confined in a wire cage, and supplied with food. The receiver was perfectly free from carbonic acid during the whole experiment, and the amount of the latter gas was estimated from time to time, and noted. During the whole time the mice remained remarkably tranquil, and no remarkable difference was observed in the character of the respirations.

The amount of oxygen absorbed when air is breathed is placed by Pflüger at nine-tenths of the amount absorbed when oxygen is breathed. Gréhant³ found, however, the amount very much greater in the latter case, and considers the increase, $\frac{16}{26}$, due to the rapidity of the circulation and activity of the respiratory movements, which cause a frequent renewal. It must be remembered, however, that frequent renewals of the air in artificial respiration is attended with a diminution of the carbonic acid contained in the blood and in the air-cells; and thus the stimulus is diminished. It is well known that if, by the power of the will,

the number of normal inspirations be increased, the amount of carbonic acid expired is increased. Czermak points to this fact in connexion with Rosenthal's experiments. He says:—"If in tranquil respiration I make 3-4 respirations in 15 seconds, and interrupt the breathing by a final deep inspiration, I succeed in keeping my breath for 30-35 seconds, then, however, the respiratory necessity forces me to continue respiration. If, on the other hand, I make 15-18 complete respirations in 15 seconds, and again interrupt my breathing with a similar deep inspiration, I am enabled to retain my breath for another half minute or minute before I am forced by the same degree of respiratory need to resume my respiration."¹

The amount of oxygen absorbed by the blood varies, according to the experiments of M. Gréhant, in different apparently healthy animals of the same species (thus the volume per cent, that could be absorbed he found in one case 18.8, and in another 31.3), and is proportional to the amount of hæmoglobin in the blood.

The experiments of von Lesser, performed in the Leipzig laboratory, show that many circumstances affect the amount of hæmoglobin in the blood. The amount of hæmoglobin in the large arteries and large veins, at the same time and under the same circumstances, is the same. A variation in the rapidity of the flow of blood in the arteries, due to increase in the peripheral resistance or variation in the number of heart heats, produces no change. The amount of hæmoglobin in the blood-current is dependent on such variations in tension in the arterial system as serve to diminish or increase quantitatively the flow of blood to the right heart. This observer has shown that the abstraction of blood, provided that it does not exceed a certain amount, does not diminish the amount of hæmoglobin. Tying an animal in the recumbent position, produces a transitional increase and decrease. The cutting and stimulation of the spinal cord affects the amount of hæmoglobin in so far as it affects the flow of blood to the right heart. Tying the portal vein is attended with a diminution in the amount of hæmoglobin in the arterial system; this diminution takes place with a variable degree of rapidity depending on the vascular connexions of the vena portæ. The diminution is apparently more rapid than the sinking of the arterial pressure. Interruption of the circulation in the lower extremity is attended with somewhat variable results.²

These experiments prove that the number of corpuscles in the arterial and venous system is subject to variation, and that it is dependent upon such a variation in the tension of the vascular system as increases or diminishes the flow of blood to the right heart; and

this tension is, within certain limits, under the control of the nervous system.

In making an estimation, therefore, of the amount of oxygen contained in the blood under different circumstances, it is necessary to take account of the amount of hæmoglobin contained in the blood-stream. Thus, if the number of blood-corpuscles in any part of the system be increased, more oxygen, *cæteris paribus*, will be found in that part of the system, and if less blood-corpuscles, then less oxygen will be present. An alteration in the relation of the blood-corpuscles to the capillary walls is regarded by some as a result of deficient oxygenation.

In this respect their condition is, to some extent, comparable to the relative conditions of the blood and blood-vessels in inflammation. In the latter, in the second stage, a massing of the red blood-discs takes place in the capillaries. This phenomenon, which was regarded by Lister to be of the same nature as the formation of rouleaux in blood that is drawn, has been shown by other observers to depend, in part or altogether, on an alteration in the capillary walls.¹

A change in the distribution of the blood-corpuscles in the state of asphyxia, which would be attended with the withdrawal of an appreciable number of blood-discs from the larger arteries and veins, would necessarily, other things being the same, lead to a diminution in the amount of oxygen in the larger veins and arteries. An estimation of the amount of oxygen in the larger arteries and veins would, in that case, require correction before it could be taken as a sign of the oxygenation of the general mass of blood.

In the condition of apnœa, on the contrary, the diminution in the amount of the carbonic acid in the blood produces necessarily an alteration in the relation of the blood to the capillaries. If such an alteration be attended with a withdrawal of the blood-discs from the capillaries and an increase of these elements in the larger arteries, then the amount of oxygen, as given by an analysis of the blood in the larger vessels, is too high, if it be taken as a sign of the oxygenation of the general mass of the blood.

Pflüger has shown that the colour of the blood depends on the number of corpuscles present, as well as the gas contents.² The venous blood in apnœa is frequently dark in colour—a circumstance attributed by Finkler and Oertmann³ to the character of the artificial respiration and the nature of the heart's action. They showed that if the animal be placed in a warm bath the venous blood becomes red. This may be accounted for in two ways. The effect of the warm bath is to cause dilatation of the capillaries, and the blood that passes into the veins has more oxygen, and the heart's action is at the same time increased by the heat (Finkler and

Oertmann); or the change in the colour of the blood, from dark red to bright red, may be accounted for by supposing the heat to produce such alteration in the walls of the capillaries as leads to a dilatation of these vessels and an accumulation of red blood-corpuscles in them.

In this case the number of blood-discs in the larger vessels would be reduced, and a brightening in the colour would result—so that if such an alteration in the general distribution of the red blood-corpuscles takes place in asphyxia and apnœa, the number of oxygen carriers in the larger vessels in the former case is diminished, and in the latter increased, whilst the total number in the blood may be unaltered.

The velocity of various fluids through capillary tubes must be regarded as an important element in the determination of the general condition of the blood, from an analysis of a portion of blood taken from a large vein or artery during the condition of apnœa or asphyxia.¹

It is necessary to take a glance at the mechanical means used to produce apnœa. Artificial respiration differs from ordinary respiration in this way, that in the former the air is used to force out the lungs and chest walls, and in the latter the expansion of the chest and lungs draws in the air. The force used in drawing air into the lungs, and which acts upon the various tissues in the air passages and chest walls, produces the simple mechanical effects of pressure upon the terminations of nerves in their structures, or by expanding the muscular and elastic tissues of which the lungs and pareties are composed, alters the condition of the nerves supplied to these structures. The state of expansion of the chest walls and lungs acts as a stimulus to the expiratory (inhibitory) nerves of respiration, and the state of contraction acts as a stimulus to the inspiratory nerves² (Hering and Langendorff). The effect of artificial respiration is to stimulate the nerves distributed to chest walls, diaphragm, and air passages, so as to produce an inhibitory action, and in this way the active inspiratory agents become quiescent. The experiments of Brown-Séquard made with a view to determine the cause of the arrest of strychnia tetanus under certain circumstances, support this theory. Brown-Séquard confirmed the observations of Rosenthal and Leube, that insufflation arrests strychnia tetanus, but differs from these observers with regard to the cause. Rosenthal considered the arrest to be due to the increase in the oxygen in the blood. Brown-Séquard found that the mechanical effect of insufflation upon the terminations of the vagi and the nerves of the diaphragm was the cause of the cessation of the tetanic spasms, since insufflation was without effect after division of the vagi and section of the spinal cord above

¹ Dr. Sanderson, in Holmes' Surgery. Vol. V., p. 757.

² Archiv. B. I.

³ Op. cit.

¹ Annales de Chimie. III., XXI., 76.

² Du Bois Reymond's Archiv. 1879.

and below the origin of the phrenic nerves.¹ Thus it is seen that insufflation has a distinct inhibitory effect upon muscular contraction, and this by the stimulation of the terminations of the nerves supplied to the air-passages and diaphragm. The respiratory centres then can be excited in many ways. Oxygen diminishes, carbonic acid excites, respiratory action. As the oxygen is carried to the respiratory centres by the blood-discs, the fewer the number of blood-corpuscles that travel to the medulla, and the less oxygen they contain, the respiratory centre receives the greater stimulus. Increase in the amount of oxygen in the blood-corpuscles and increase their velocity will compensate for a diminished number. An increased velocity can be obtained by an increased action of the heart, and an increase of oxygen by more perfect aëration.

Artificial respiration acts in two ways upon the nerve-centres. The carbonic acid contained in the blood and air-passages is diminished, so that the nerve-centres lose the stimulus due to the action of carbonic acid on the respiratory centres; secondly, the pressure of the air forced into the lungs upon the nerve terminations in the bronchi, &c., produced an inhibitory effect upon certain respiratory structures.

R. F. Dill, President

Ninth Meeting was held upon Tuesday the 27th inst. April 1880.

Present, Professor Dill M.D. President, Drs. J. W. Browne and Fagan Vice-Presidents, Drs. Esler, Withers, Kevin, Dempsey, Wales Jnr., Whitla, Harkin.

Dr. Withers read a paper upon sulpho-carbolates in the treatment of zymotic disease.

Paper:² MR. President and Gentlemen,—I am happy in having the liberty of bringing before you some results obtained from the administration of the sulpho-carbolates in several diseases—as smallpox, scarlatina, and acute tonsillitis. I am the more encouraged to do so as this plan of treatment of zymotic disease has not—at least in this country—been much advocated or known; and, also, since any branch of the therapeutics of germ diseases should be carefully thought of, and well tested.

My attention to these preparations was first directed by Dr. Seaton Reid, to whom I owe much valuable information.

The sulpho-carbolates, as therapeutic agents, were first introduced by Sansome and Crookes in 1867, but their valuable properties have not as yet been generally recognised, and the advantages possessed by them over the sulphites and carbolates call upon an investigation into, and a clinical test of, their merits as members of that great division of therapeutics—the antiseptic system. These advantages are as follow:—They are very stable salts, almost tasteless, soluble to any extent,

easily absorbed by the blood, and at the same time are also antiseptic.

The sulpho-carbolates are formed usually by the union of oxides or carbonates of metals, or alkaline earths or alkalies, with a compound acid named sulpho-carbolic acid. This acid ($C_6H_6SO_4$) is prepared by mixing atomic weights of pure carbolic acid and pure sulphuric acid; however, it is better to add the sulphuric acid slightly in excess, as the compound acid then obtained forms, with the metallic or alkaline base, crystals of a better form. Heat is evolved, and in a short time a dark syrupy fluid is the consequence. After three or four hours, by slow crystallisation, the pure acid may be obtained in long colourless needles, which are readily deliquescent. The sp. gr. of the acid is 1.288, the odour is less intense than that of carbolic acid, and has an acid reaction; the iron test is also more readily manifest than in the carbolic acid alone. It is soluble in water, alcohol, and ether to any extent.

Perhaps it may be well to state the mode of preparation of the salts which I have the honour to place before you.

1st. The zinc sulpho-carbolate— $Zn(C_6H_5)SO_4$. By taking pure sulpho-carbolic acid, and adding oxide of zinc, or pure metallic zinc, until the acid is thoroughly saturated, hydrogen is given off during the process, and by slow evaporation we obtain crystals, in the form of brilliant, colourless, rectangular plates, which are very soluble.

2nd. Iron sulpho-carbolate— $Fe(C_6H_5)SO_4$ —is prepared by acting on the pure iron with sulpho-carbolic acid to neutralisation, and then crystallising. The crystals obtained are in the form of plates of a light green colour, and readily soluble in water.

3rd. Sodium sulpho-carbolate— $Na(C_6H_5)SO_4$ —It is the best known of the series, and is obtained by neutralisation of the acid with carbonate of soda, then evaporating carefully over a water bath. The crystals are brilliant rhombic prisms, soluble in two-thirds their weight of water, slightly soluble in alcohol, but not in ether. The pure salt is tasteless.

The sulpho-carbolates should all yield clear solutions, and have a definite crystalline form. There should not be the least odour of carbolic acid, but on heating carbolic acid is given off. They are also very stable compounds.

In endeavouring to advocate the further and more extensive use of these agents in general practice, I have a few introductory remarks to make before I proceed to state what clinical experience has revealed. You will agree with me that each zymotic disease is the result of a specific poison, which is stated to be in the form of a germ; the action of this poison I believe to be more fermentative than catalytic, so that believers in the germ theory of disease are more clearly recognising the fact that a new era has arisen in the science of therapeutic medicine—that is, if the germ theory be correct, then

¹ Ringer. Therapeutics. P. 561.

² [Dublin Journal of Medical Science, 1880, v70, p354.]

there can be laid down the principle that antiseptics and antiferments will be valuable in the treatment of zymotic disease. To enter into an explanation and defence of the germ theory would be outside the limits of this paper, but I shall merely say that I believe that most of the cases of contagious diseases arise by means of a previous germ—so that if, when this is introduced into the system, it be acted on by a soluble antiseptic, then I am convinced the zymotic poison will be modified in its effects, and its duration shortened.

To obtain a suitable agent, having the above quality, has long been a desideratum; in carbolic acid, however, I think we find what is required, but the difficulty with it is to administer it internally without some unpleasant effects, so that the tissues which have been impregnated with the zymotic poison may absorb the antiseptic. This objection is got over in the combination sulpho-carbolate, which, however, is not a direct antiseptic itself, yet, when it is absorbed, the carbolic acid of the salts is thoroughly projected through the system, and a sulphate excreted by the kidneys and intestine. The sodium salt is the most powerful in arresting saccharine fermentation, and as it is very soluble and tasteless, it has been the most extensively used. I have seen no ill effects from its administration, in scruple doses, every four hours. After being taken for a short time, the odour of carbolic acid can be detected in the breath. I have also noticed a slight looseness of the evacuations occasionally, which I would attribute to the sulphate of sodium after the carbolic acid has been set free.

For some time past scarlatina, smallpox, and acute tonsillitis (which, indeed, in many cases might be classed as the result of a zymotic poison) have been treated in the Union Fever Hospital with the sulpho-carbolate of sodium. Statistics, I am aware, are often not reliable, but as the action of this salt has been so remarkable, I will take the liberty of placing before you some statistical details.

Cases of scarlatina on admission receive a tepid bath, and the treatment adopted is the sulpho-carbolate of soda in solution. No other remedy is prescribed except in cases of hæmorrhage. The diet is milk. The dose of the sulpho-carbolate is 10 grs. every two hours; 5 grs. for children. Since its introduction into the Fever Hospital, 31 cases of scarlatina have been admitted. Of course these were not all of a malignant type, more than one-half being of the simple form of scarlatina, which is said by some to get well without any treatment; however, during the progress of the fever, advantages in the above treatment have been noticed which will place this medicinal agent far in preference to others.

Of these 31 cases there were 3 deaths, which will make a mortality of 9.7 per cent. This I think is a low death-rate, when we consider that about one-quarter of the cases were of an anginous or malignant charac-

ter. The results of this special treatment in these 31 cases have been almost unvaried. The absorption of the sulpho-carbolate of soda into the system is noticed at about the end of twenty-four hours, by the evidence of an almost complete cessation of throat symptoms. The tonsils are of a dirty white colour, as if touched with a mild caustic, and their enlargement is observed to diminish quickly. The temperature and general fever lessen, and the patient proceeds rapidly to convalescence.

Since the commencement of this treatment in no case have I noticed any dropsy, and in the majority there was very slight, if any, desquamation. I have, therefore, every confidence in the substitution of the sulpho-carbolate as an antiseptic antipyretic in the place of the former diaphoretic and expectant treatment of scarlatina. It has been most satisfactory, the recovery of the patients being rapid and complete, and the mortality rate being very low.

The next disease on which we have tried the influence of sulpho-carbolate of soda was smallpox. We were unfortunate during the epidemic of 1878 in not having this preparation in our possession, as then statistics of 156 cases might have been prepared which would have shown more perfectly the reliance that can be placed in it; but, however, in a few cases towards the latter part of the epidemic, and in some recent cases, it has been administered with marked success. These cases were 25 in number, and of them we had 2 deaths, one a young man in whom the disease was confluent and hæmorrhagic, and the other a child of four months old, ill with marasmus, and who received the variolous poison from its wet nurse. You will see we have thus a death-rate of 8 per cent. These cases are taken successively, without any selection, and when we take the last 25 cases of the epidemic of 1878, when it might be expected that the type of the disease would be less severe, it is found that the death-rate was 16 per cent. The rate of mortality for the 156 cases admitted into hospital in 1878 was 19.87 per cent; whilst that for the whole borough was 26 per cent.

Now if we pursue the argument that mortality rates are decisive as to treatment, there can be no doubt as to the proper value of the sulpho-carbolate, but they are often delusive. The internal treatment is similar to that of scarlatina, but occasionally an alcoholic stimulant or a sedative is required. It has been found that when the patient is seen early, and treatment at once commenced, then the primary fever is lessened, the throat symptoms which are so troublesome to a smallpox patient, when the soft palate and fauces are covered with pustules, disappear rapidly—often in twelve hours—and, what is more remarkable, in none of the cases so treated has any secondary fever been observed. I cannot say that the internal administration of the sulpho-carbolate has any effects on the scars of the pustules, and we have not tried the external application

of carbolic acid to the pustules, as has been done in Dublin. The effects of this treatment have been so uniformly successful as to warrant me in adding my testimony in favour of its employment in smallpox.

In acute tonsillitis the administration of sulpho-carbolate of sodium was eminently favourable, the hypertrophy of the tonsils rapidly subsided, rarely is there any suppuration, and power of swallowing is restored in from three to four days. It is in this affection that I think the iron salt will prove most useful, as I have noticed cases where the patient was much prostrated—in fact, in a typhoid condition; and I believe that the administration of the iron preparation will be more satisfactory than the sodium salt, although the latter is very beneficial when combined with quinine.

As for the employment of the sulpho-carbolates in other contagious diseases I have had no experience, but I believe that Ligertwood has administered them in typhoid fever and phthisis with very varying success.

Passing on from the practical to the suggestive, I would ask the attention of the Society to another of these salts—viz., the sulpho-carbolate of calcium. In the treatment of rickets, it has been difficult to find a reliable soluble lime salt. Those generally within our reach are not so, and contain but small quantities of lime, whereas we have in this a salt which is easily soluble in its own weight of water, and containing ninety grains of calcium in the ounce of the sulpho-carbolate. Hence, by this means, we are enabled to introduce lime into the system to any extent, so that I would suggest that this agent should be employed in those diseases of the bones which are marked by a deficiency in the lime salts; for the usual salts employed are deficient in solubility, and allow but of the absorption of the lime in too feeble proportions to be of any practical value.

As for the zinc sulpho-carbolate, I have not seen it employed sufficiently as to warrant any certain conclusion. But Professor Wood recommends its use for ulcers and wounds, in solutions of 5 to 10 grs. to the ounce of water, inasmuch as the fluids of the wound slowly decompose the salt, and set free the carbolic acid, which, acting as a germ destroyer on the surface of the wound, and in the surrounding atmosphere, rids them of all putrefactive particles, whilst at the same time the metallic salt is exerting its own inherent antiseptic and astringent qualities.

In conclusion, gentlemen, whilst we try to avoid, on every hand, by a cautious and prudent abstinence, all extremes, we must have a constant regard for the results of actual experience. These extremes, on the one side, might be a violent advocacy of the germ theory of disease and the attendant therapeutics; or, on the other, quite as violent and total denunciation; yet, whether our position be one or other of these matters little in the consideration of the advantages which arise from the administration of the sulpho-carbolates. In no sense can we be accused of undue influence when there

is but a simply-stated clinical experience. This experience, no doubt, limited so far, will extend and approve of the use of these agents. Experience keeps hand in hand with theory.

The underbasement of the discovery of these preparations was the antiseptic theory, and still keeping in view a knowledge of this, have their qualities been advocated. Any theory which might be advanced to explain their action might, perhaps, be set aside by the exponents of the pro or con, but I venture to submit that it is to the ready solubility of the salts and to the antiseptic character of the carbolic acid that we must attribute their undoubted value. Why these salts seem to act principally on the throat would not be easy to say; but I would suggest, that it is because our attention in the above diseases is directed mainly to the throat, and, hence, here we look for the first improvement, and the patient first expresses his relief in having the throat symptoms subdued. I believe that the medicinal agent induces a total reaction throughout the entire absorbent system, but that owing to the inflammatory action taking so acute a form in the region of the tonsils, it is here we experience the earliest benefit.

The therapeutical action of the sulpho-carbolates I would thus summarise:—The soda salt, so far, has proved a powerful agent in curtailing the natural course of the disease, in subduing the pyrexial condition accompanying zymotic affections, and, lastly, there is an obvious and distinct alleviating influence on the throat symptoms. The iron salt, not yet so much in use, has been beneficial as a tonic antiseptic. Whether its action in those cases of phthisis where there is abundant fetid expectoration will be advantageous, is a point to be determined in the light of future experience.

The zinc and calcium sulpho-carbolates, are still, I may say, in their infancy as surgical remedies, but will, I am sure, be taken up, and fulfil the expectations of those who have brought them forward as therapeutical agents.

Gentlemen, I have no doubt of the usefulness of the sulpho-carbolates, but you will please understand me, that I do not consider them to be infallible in the treatment of zymotic disease. Everyone has met with rapid and deadly cases of infection, where every form of treatment was hopeless. My idea in preparing this paper was to add a tittle of evidence to the growing opinion that the treatment of zymotic diseases must, in the future, be such as to deal with the fever itself, and not with symptoms—or, in other words, expectant treatment must be consigned to oblivion.

Dr. Fagan showed three patients: one with a drainage tube through the os calcis for 18 months; one whose knee joint had been excised; and one whose os calcis been removed; and gave an account of the previous history of the three cases.

R. F. Dill, President

Tenth Meeting was held in the Belfast Royal Hospital upon the 22nd of June 1880.

President Dr. Dill in the chair. Present Drs. Harkin, C. D. Purdon, Wales Snr., Dempsey, McKee, Kevin, Esler, Wadsworth, Whitla.

Dr. Harkin brought up a matter in connection with apothecaries' privileges in compounding but after some remarks he consented to bring it up in another form at a future period.

Dr. C. D. Purdon read a paper upon the infantile death rate of Belfast and suburbs for the 10 years 1864–73 with tabular statements and classifications of the various diseases causing death.

Paper:¹ THE necessity of inquiring into the diseases that cause the great mortality amongst children under 2½ years of age, was forced on my attention by the desire that was expressed in a late meeting of the Medical Officers of Health at one of their annual reunions.

So in examining the register of the Belfast Factory district along with my friend, Dr. Newett, of Ligoniel, for the purpose of ascertaining the relative mortality of the various classes into which the population is divided—viz., the Factory, Artisan, and Labouring, the Professional, Mercantile, and Gentry—I considered it advisable to ascertain the death rate according to the births in each class. As the great mortality among infants is under 2½ years, and as after this period the critical affections of infancy are generally over, I have selected that time as the limitation under this head for my investigation, dividing this period under two general heads—viz., deaths occurring under 1 year and under 2½ years. As the district consists of a town and country division, I have kept the death rates separate, so as to enable the reader to compare the relative mortality in each. In all the tables that I have seen the death rate has been given without specifying the diseases; so, in the first place, I have given the entire death rate in the town and country according to the number of births, without specifying the diseases; and, in the second place, the four diseases in which I have classed the various causes of death in each class, showing the relative percentage of deaths from each disease in each class under one year and the next year and a half.

The tables have been made for 10 years, from 1864 to 1873 inclusive, and are divided into two equal periods. In the first quinquade the number of births in town in the factory class was 2,221; in the artisan, &c., 22,780; in the gentry, 551—total, 25,552. In the second quinquade the births in the factory, 2,737; in the artisan, &c., 28,206; in the professional, middle, &c., 772—total, 31,715; total for 10 years, 57,267.

In the country districts—viz., Ligoniel, Whitehouse, and Carnmoney, in the first quinquade, the births in the factory class were 527; artisan, &c., 1,978; professional and gentry, &c., 107—total, 2,612. In the second

quinquade, in the factory class, the births were 486; in the artisan, &c., 1,804; in the professional, gentry, &c., 68—total, 2,358; total for 10 years, 4,970. This sum added to the number that were born in the town districts, gives a total number of births of 62,237. In the factory district the statistics are calculated according to the births per centum; so taking the deaths from all causes in the town districts among the factory class under 1 year in the first quinquade, we find it amounts to 14.5 per cent.; in the next 1½ years, 6.7 per cent.—total, 21.2. In the second quinquade, under 1 year, 22.8 per cent.; in the next 1½ years, 7.3 per cent.—total, 30.1 per cent.; average death-rate for 10 years amounts to 26.1 per cent. In the artisan and labouring classes the average death-rate amounts, in the first quinquade, under 1 year, to 15.9 per cent.; in the next 1½ years, 7.8—total average, 23.7 per cent. In the second quinquade, average under 1 year, 16.9 per cent.; in the next 1½ years, 8.1—total average, 25.0.

In the mercantile, &c., total average of deaths in the first quinquade, under 1 year, was 5.8; in the next 1½ years, 2.3—total average, 8.1. In the second quinquade, deaths under 1 year, 18.9 per cent.; in the next 1½ years, 4.1—total average, 23.0. I may mention that scarlatina was a complete scourge during this period.

In the country districts the causes of death in the factory class, under 1 year, for the first quinquade, the average amounted to 17.8 per cent.; in the next 1½ years, amounted to 8.2 per cent. In the second quinquade the average was 16.7 per cent. for those under 1 year; in the next 1½ year the average was 7.4 per cent., making, in the first period, a total of 26.0 per cent.; in the second period, 24.1 per cent.

In the artisan and labouring classes the average percentage of deaths, under 1 year, in the first quinquade was 12.3; in the next 1½ years, 4.9 per cent. In the second quinquade the average, under 1 year, was 13.7 per cent.; in the next 1½ years, 5.9 per cent., making a total, in the first period, of 17.2 per cent.; in the second, 19.6 per cent.

In the professional, mercantile, and gentry, the average percentage of deaths, in the first quinquade, under 1 year, was 5.6 per cent.; in the next 1½ years, 2.8 per cent. In the second quinquade the average of deaths, under 1 year, was 14.7 (caused by zymotic diseases); in the next 1½ years, 4.4 per cent., making a total of 8.4 per cent., for the first period, and 19.1 per cent., for the second.

In order to ascertain the relative mortality from various diseases I have divided the causes of death into four general heads—viz., Inflammatory (Surgical), Zymotic, Phthisis and diseases of the respiratory organs, and Neurotic disease, keeping the classes and districts separate as before, also dividing them into two quinquades.

In the town districts, in the factory class, the average death rate from Inflammatory affections in the first

¹ [Dublin Journal of Medical Science, 1880, v70, p530.]

TABLE NO. 1.—Infantile Mortality in Castlereagh District.

	251	45	17.9	16	6.4	24.3	5,426	759	14.0	375	6.9	20.9	76	8	10.5	8	10.5	21.0

quinquade was 3.1 per cent., under 1 year, in the next 1½ years was 1.7 per cent.; in the second quinquade, under 1 year, was 4.6 per cent., in the next 1½ years was 1.5 per cent.

From Zymotic disease, in the first quinquade, the average death rate was 2.8 per cent. under 1 year, in the next 1½ years 2.2 per cent.; in the second quinquade the average death rate, under 1 year, was 4.3 per cent., in the next 1½ years 2.4 per cent.

From Phthisis, &c., the average death rate, in the first quinquade, under 1 year, was 4.5 per cent., in the next years 1.9 per cent.; in the second quinquade, under 1 year, 9.2 per cent., in the next 1½ years 2.6 per cent.

From Neurotic affections the average death rate in the first quinquade, under 1 year, was 4.1 per cent., in the next 1½ years 0.9 per cent.; in the second quinquade, under 1 year, was 4.5 per cent., in the next 1½ years 1.0 per cent.

In the artisan and labouring class the average death rate from Inflammatory affections in the first quinquade was 3.3 per cent., in the next 1½ years 2.1 per cent.; in the second quinquade was 3.7 per cent., in the next 1½ years 1.8 per cent.

From Zymotic diseases the average death rate in the first quinquade, under 1 year, was 2.9 per cent., in the next 1½ year 2.6 per cent.; in the second quinquade, under 1 year, 2.7 per cent., in the next 1½ year 2.7 per cent.

From Phthisis, &c., the average death rate in the first quinquade, under 1 year, was 5.8 per cent., in the next 1½ year 2.2 per cent.; in the second quinquade, under 1 year, the average death rate was 7.2 per cent., in the next 1½ year 2.4 per cent.

From Neurotic diseases the average death rate,

under 1 year, in the first quinquade was 3.7 per cent., in the next 1½ year 1.0 per cent.; in the second quinquade the average death rate, under 1 year, was 3.2 per cent., in the next 1½ year 1.1 per cent.

In the gentry, &c., classes the death rate from Inflammatory affections in the first quinquade, under 1 year, was 1.2 per cent., in the next 1½ year 0.4 per cent.; in the second quinquade, under 1 year, the average death rate was 6.7 per cent., in the next 1½ year 1.5 per cent.

From Zymotic diseases the average death rate in the first quinquade, under 1 year, was 0.5 per cent., in the next 1½ year 1.2 per cent.; in the second quinquade, under 1 year, the death rate was 3.4 per cent., in the next 1½ year 0.6 per cent.

From Phthisis, &c., the average death rate, in the first quinquade, under 1 year, was 1.8 per cent., in the next 1½ years .0; in the second quinquade the average death rate under 1 year was 5.4 per cent., in the next 1½ years 1.5 per cent.

From Neurotic diseases the average death rate, under 1 year, in the first quinquade was 2.4 per cent., in the next 1½ years 1.2 per cent.; in the next quinquade the average death rate under 1 year was 3.2 per cent., in the next 1½ years 0.5 per cent.

In the country districts, in the factory class, the average death rate, under 1 year, from Inflammatory affections, in the first quinquade, was 4.7 per cent., in the next 1½ years 2.8 per cent.; in the second quinquade the death rate under 1 year was 2.9 per cent., in the next 1½ years 1.6.

From Zymotic diseases the average death rate, in the first quinquade, under 1 year, was 2.6 per cent., in the next 1½ years 1.7 per cent.; in the second quin-

quinquade the average death rate under 1 year was 3.3 per cent., in the next 1½ years 0.8 per cent.

In the artisan and middle classes the average death rate, from Inflammatory diseases, under 1 year, in the first quinquade, was 3.2 per cent., in the next 1½ years 1.6 per cent.; in the second quinquade the average death rate under 1 year was 2.9, in the next 1½ years

2.3 per cent.

From Zymotic diseases the average death rate, under 1 year, in the first quinquade, was 1.4 per cent., in the next 1½ years 1.4 per cent.; in the second quinquade the average death rate under 1 year was 1.1 per cent., in the next 1½ years 1.4 per cent.

From Phthisis, &c., the average death rate, in the

INFANTILE MORTALITY.

first quinquade, under 1 year, was 3.8 per cent., in the next 1½ years 1.4 per cent.; in the second quinquade the average death rate under 1 year was 6.9 per cent., in the next 1½ years it was 1.7 per cent.

From Neurotic affections the average death rate, in the first quinquade, under 1 year, was 3.8 per cent., in the next 1½ years 0.6 per cent.; in the second quinquade the average death rate under 1 year was 2.8 per cent., in the next 1½ years 0.5 per cent.

In the gentry, professional, and mercantile classes the average death rate from Inflammatory affections, in the first quinquade, under 1 year, was 2.1 per cent., in the next 1½ years .0; in the second quinquade the average death rate under 1 year was 2.9 per cent., in the next 1½ years 2.9 per cent.

From Zymotic affections, in the first and second quinquades, there were no deaths in the two periods.

From Phtisis the average death rate, in the first quinquade, under 1 year, was 1.9 per cent., in the next 1½ years .0 per cent.; in the second quinquade the average death rate under 1 year was 8.8 per cent., in the next 1½ years 1.5 per cent.

From Neurotic diseases the average death rate, in the first quinquade, under 1 year, was 1.9 per cent., in the next 1½ years 1.9 per cent.; in the second quinquade the average death rate, under 1 year, was 1.5 per

cent., in the next 1½ years 1.5 per cent.

Such are the results that have appeared from the examination of the registries of the district, which show that the mortality among the infants is so great that special attention should be directed to the exciting causes of those diseases that annually carry off so many of our young to an untimely grave; but though the Legislature has been forced by the representations of medical societies to do a good deal in favour of society, yet more is required at their hands before our infant population is placed in a proper sanitary state. I regret very much that I have not been able to give during this period the state of the barometer, thermometer, wind, and rain—four great factors of our health:—

J. Walton Browne

**Annual Meeting Session '79-'80
6th July 1880.**

Present, Dr. Dill (President), Dr. Harkin, Dr. Moore, Dr. Whitla, Dr. O'Neill, Dr. McKenzie, Dr. Kevin, Dr. Core, Dr. Wadsworth, Dr. Dempsey, Dr. Esler, Dr. Wales Snr., Dr. Workman.

The report of the Council was read and on the motion of Dr. Harkin seconded by Dr. Moore was adopted.

Ulster Medical Society
Session 1879–1880
President Robert Foster Dill

The Treasurer's report was read. Dr. Dempsey moved and Dr. O'Neill seconded its adoption which was carried unanimously.

The Librarian's report was read and on the motion of Dr. Harkin seconded by Dr. Esler was adopted.

Proposed by Dr. O'Neill seconded by Dr. McKenzie that the Librarian and Secretary issue a notice to the members that the Library is now available.

Dr. Harkin moved and Dr. Wales seconded that Dr. J. W. Browne be appointed President carried by acclamation.

Dr. Fagan (10 votes) Dr. McKeown (9 votes) were appointed Vice-Presidents.

Drs. Harkin, Clements, O'Neill, Wales, Moore, and Dempsey were appointed members of Council.

Proposed by Dr. O'Neill and seconded by Dr. Esler that Dr. Workman be appointed Assistant Librarian and carried.

Proposed by Dr. Moore and seconded by Dr. Wales that the thanks of this Society be given to Dr. Whitla and Dr. Esler and that they be appointed Secretary and Treasurer for the ensuing year.

Proposed by Dr. Esler and seconded by Dr. Wales that Dr. McKenzie and Dr. Kevin be appointed Auditors.

Dr. Harkin gave an extract of his paper on "Chlorate of potash—its therapeutic action".

Paper:¹ As chlorate of potassium exerts a salutary influence on all vital phenomena, especially upon the processes of cell growth, nutrition, and secretion, we might naturally expect to find that its administration in an abnormal condition of the conglomerate glands would be followed by evidence of its power; and such is the case, for example, in functional derangement of the salivary and mammary glands.

The first-named may fail in secreting power from congenital defect as in a class recognised by naturalists as dry-mouthed families, or from the effects of wasting diseases, such as diabetes. They may, on the other hand, from various causes, suffer from an excess of secretion, as in the period of dentition, and its opposite, old age; from sialogogues, such as mercury, pellitory of Spain, and tobacco. The sight and smell of savoury viands have the same effect.

In either case—whether that of ptyalism or its opposite condition—chlorate of potassium, taken internally, restores the balance and regulates the condition. Its primary effect in the healthy state is to stimulate and increase the flow of saliva, many persons being inconvenienced by swollen gums while taking it; and, when required and given in the form of lozenge or solution, it restores the absent or failing secretion. We are all conversant with the controlling power of this remedy in cases of mercurial salivation, but mistake its *modus operandi* when we attribute its action to an

antidotal opposition—to mercury, as in the example of opium and belladonna. The salt simply acts as a regulator—in the first instance exalting the physiological power when below par, and in the second by reducing to normal limits the working of the gland when in an excited condition.

This statement may appear, at first sight, contradictory and unreasonable. The exhibition of digitalis in neurotic affections of the heart affords a parallel case—at one time given to restrain excessive energy of the organ, and, again, to increase the effective force of the heart. The mammary gland in the nursing mother is also obnoxious to two opposite conditions—agalacty, or the absence or paucity of secretion, and galactorrhœa, or excessive secretion, and either of these states gives rise to suffering and discontent in the case of the nursing mother; and although no secretion is more readily modified in its physical qualities by the nature of the ingesta, varying as the nature of the food, whether principally animal or vegetable, or more readily affected by purgatives, saline or otherwise, yet there are few remedies which possess the power of increasing the secretion or of controlling its over-production. Chlorate of potassium has the desired efficacy; it will do all that is promised for *jaborandi* and more, for its use in regulated doses will rarely fail either to elevate or reduce the secretion to the desired standard as required. In the nursing mother it seems that the blood is sent to the breast in larger quantities in a given period, while, at the same time, the exhalant properties of the skin and kidneys are diminished. Medicines, which in the ordinary state get into the circulation and pass off by the kidneys, are found less plentifully in the urine, and are carried to the mamma, and thus produce in that organ their tonic and stimulating effects. I have, times without number, prescribed this remedy when the milk was insufficient or totally absent, and have been often entreated, a few days after, to allow the nurse to intermit its use, from the painful and bursting feeling of the teeming breasts. The influence of the remedy as a galactagogue appears limited to the first three months of lactation, and there are some constitutions quite uninfluenced by its use. I believe it shows its power more completely in women of the sanguine temperament, the gland enlarging rapidly and secreting freely under its influence in their cases. A collateral advantage always pertaining to it is, that the nursing improves marvellously, as it shares in the benefit of the salt which it imbibes with its mother's milk—no fact having been better established than that medicinal substances, mineral and vegetable, are discoverable by chemical analysis in the mother's milk, and their physiological influence is demonstrated by their effects on the baby. Out of a number, I shall submit an example of the efficacy of the remedy in the opposite states:—

Case I.—Agalacty.—Some years since, Mrs. J., living in Fleetwood-street, had been attended by me in three

¹ [Dublin Journal of Medical Science, 1880, v70, p403.]

confinements, each time of a daughter. On the first occasion there was not even an attempt made to secrete milk, and in the two succeeding births the secretion was merely nominal. At length a fourth child, a boy, was born, and the mother had a most intense desire to nurse him, but in vain. After a week I prescribed a mixture composed of an ounce of the chlorate to a pint of water, ordering one-half wineglassful to be given three times daily, with the result that before the expiry of three days, and ere the mixture was exhausted, the baby had to be brought to relieve the over-distended breasts. This child was nursed successfully for several months.

Case II.—Galactorrhœa.—Mrs. B., residing in Donegall-street, was confined of twins in her first labour. She had very large breasts, and after the first week the secretion was so profuse that the twins were unable to relieve her; night and day she was in a perpetual bath, and she often found it necessary three times after retiring to rest to change completely her night-dress. I prescribed the remedy in a similar quantity and dose, and in a few days the secretion was controlled to her full satisfaction.

There is a condition well known to the profession in which ladies complain to their medical adviser of debility and wasting, night perspirations, palpitation and pain in the left side under the mamma, due to prolonged lactation; the mother is unwilling, or unable perhaps through delicacy of the child, to consent to ablactation. In this case, so very often occurring, by the administration of the chlorate combined with the *tr. ferri perchlor.*, she may be enabled to prolong her maternal duties through the restoration of her strength, the increase of the secretion and improvement of its character, and the subsidence of the lateral pain. The influence of the medicine is not limited to the living child, but extends even to the period of intra-uterine existence—as medicines administered to the pregnant female affect undoubtedly the unborn baby. We all know that ergot administered freely to the mother three or four hours previous to birth will often result in the birth of a comatose or asphyxiated baby, quite independent altogether of the effects produced by uterine contraction—the poison acting in this case on the brain and nervous system of the foetus; and saline medicines given to the mother have often been found in the secretions of the child after birth. I have often prescribed the chlorate when the movements of the child in utero were becoming feeble, and with the best results; its efficacy, however, is best established in its power of controlling the tendency to give birth to a succession of still-born children at a premature period—cases quite distinct from those caused by a syphilitic taint. Of such I have had many memorable examples. I will adduce a remarkable one in illustration:—

Case III—On 9th January, 1869, I was called to attend Mrs. H. in her first confinement. She was in

labour at the eighth month, and soon a male child was born, without trouble, but without life. There were not any signs of syphilitic taint either in the child or the parents. On 80th March, 1870, I was again sent for, when a girl was born prematurely, caused by an accident in the street from a wild bull. When the third pregnancy was somewhat advanced I put the lady on the chlorate of potassium mixture, and at the end of the ninth month a male child, perfectly healthy, was born alive.

On December 6th, 1872, another child was born alive at full time, the mother having followed the same regime as before. On January 30th, 1874 (the mother still observing my advice), another girl was born at full time alive. On October 29th, 1875, a male child, still-born, came into the world at the eighth month, the mother believing that further medicine was unnecessary, and not having taken any. Two other children were since born alive at full time under the influence of the drug—one at December 18, 1876, and the other December 28, 1878. They are both alive at present.

It results from this, that whilst the mother followed the advice and took the prescribed remedy, a succession of living births at the full period occurred.

I think we may fairly conclude from this case that the medicine has a great efficacy in the puerperal condition, as from the moment that the medicine was taken the bad habit was arrested, that on its intermission another still-birth occurred prematurely, and that on its readoption no more fatal cases appeared. Were it necessary I could adduce many similar cases. Many years since, besides, the late Sir James Simpson also prescribed chlorate of potassium for this very purpose, on the ground that it made the maternal blood more rich in oxygen, and consequently better fitted to protect the foetus from “placental phthisis.” Other eminent gynecologists have also recommended it; and among the rest, Dr. M’Clintock, of Dublin, in an article published in the *Brit. Med. Jour.*, Oct. 13, 1877, upon “Fœtal Therapeutics,” has given a number of striking examples of its controlling power in similar cases.

Young children from the first to the sixth year, particularly those sleeping in overcrowded rooms, are subject to frequent attacks at night of screaming, with insensibility, and semi-convulsions, and somnambulism if not watched, and something approaching to the *petit mal*, due to the protracted inhalation of air deficient in oxygen and laden with carbonic acid and other morbid products—a persistence in this habit often leading to tubercle of the brain or lungs. For this condition I have always found the chlorate of potassium a sovereign remedy; and for the true convulsion and epileptic attacks of children it has proved not only curative, but, more important still, a true preventive. For the adult epileptic, although not so useful as the bromide, I have prescribed with great advantage this salt alone and in combination with the bromide.

In affections of the circulatory system, in palpitation of the heart, and in aneurism of the abdominal aorta and other large vessels, when combined with iron, most salutary results have been experienced, for by increasing the plasticity of the blood it would appear that a deposition of fibrin on the inner coat of the vessel takes place and the walls of the heart and coats of the large vessels appear as if strengthened, while the physical signs of the disease decline, and in some cases absolutely disappear.

If, according to Dr. Levinski, want of energy in the cardiac muscle is often due to the want of oxygen in the blood, we can understand how the chlorate of potassium may supply this desideratum and improve the tone of the organ. In tabes mesenterica the chlorate has a powerful effect, and in the diarrhœa and dysentery of children, when given by the mouth and by enema, the most satisfactory results have been observed in my own practice, and in that of the Vienna faculty, as published in the Rudolph Hospital Reports for 1869. Finally, in diseases of the skin, which generally are characterised by debility and a dyscrasis of the blood, the salt is a most potent remedy. In erysipelas no one is likely to question its value, particularly if combined with iron. It is equally useful in erythema nodosum, in eczema, in impetigo and purpura, in lupus when of scrofulous origin, in boils and carbuncles, in acne rosacea; and in that ailment so intractable and so troublesome to the fair sex, acne punctata, I have prescribed it with unvarying success. The remedy given internally appears to have a controlling power on the sebaceous glands and follicles, and prevents the usual progress towards suppuration. In acne rosacea the salt seems to combat the enlargement of the blood vessels and congestion of the skin, on which the disease depends. In epithelioma and cancrioid affections of the skin and mouth its efficacy as a lotion is generally acknowledged.

Dr. Workman was appointed Pathological Secretary.

J. Walton Browne M.D.

ULSTER MEDICAL SOCIETY

SESSION 1880–81

First Meeting (Session 1880–81)

9th November 1880.

President Dr. Dill outgoing President, Dr. John Walton Browne (President), Drs. Samuel Browne Snr, Wheeler, Wales, Wadsworth, Fagan, Esler, Wales Jnr., Dempsey, John Moore, Mackenzie, Aickin, Rea, Anderson, McHarry, Workman, Harkin.

Dr. Esler proposed Dr. Haslett as a member of the Society.

The outgoing President read a short address on general subjects and especially on obstetrics and gynaecology.

Paper:¹ Gentlemen,—Before retiring from this chair, and from my position as President of the Ulster Medical Society, to which I had the honour of being elected a year ago, allow me to thank you for the honour then conferred, as well as for the uniform kindness which you have so graciously and generously bestowed upon me throughout the session.

To occupy such a position—elevated to it as I was by the unanimous suffrage of the Society—is a dignity which I much appreciate, and an honour of which any member may be justly proud, especially when we consider that it is the highest compliment which the Society has in its power to confer; and I shall ever retain a grateful recollection of the hearty feeling with which your vote was accompanied, which encouraged me much in accepting of the office and of this high trust. At the same time I am free to state that I believe it was not because of any special work done by me for the Society, but it was due to the fact that I am among its oldest members, and that I had been taking an interest in the business and prosperity of the Society.

I may be permitted here to call to mind that this Society was called into existence something more than sixty years ago. Consequently it has survived what may be considered at least as two generations; and now that we are about to enter upon its sixty-second, if not its sixty-third, session, it does so, not in the infirmity or decrepitude of old age, but with as much vigour and vitality and with as much disposition for work as any previous session was ever entered upon. And why, may I not ask, should this not be so, when we have met here to-night for the purpose of installing your President-Elect, from whose young heart and cultivated intellect must flow forth an influence and force which cannot fail to inspire the whole body for work down to the most remote of its members?

At this period in the history of this Society one might feel tempted to compare the state of medical knowledge as it now stands with what it was when it first sprung into existence, but to sketch this thoroughly would require a master-hand and more leisure than I am able to command, so I leave to another the accomplishment of this great and important task. I may, however, be allowed to indicate briefly a few of the points of interest wherein the differences are found to exist between the present and past, and in doing so I think I am correct in stating that obstetric medicine and gynaecology have not been behind in the race.

On the contrary, give me leave to say that these departments have made more progress than either of the sister branches—viz., medicine and surgery. This, it will be admitted, is all the more extraordinary when we find that midwifery, including in that term gynaecology and diseases of children, has always been allowed to occupy the shady side of the profession—indeed we would be safe in asserting that it has been treated as the stepchild of medical science, and even yet it has not had that recognition to which its friends consider it is but justly or fairly entitled.

The other two departments—viz., medicine and surgery, have flourished under the fostering care of men of science and wealthy institutions, and whilst they have been thus out of proportion sustained, midwifery, it must be admitted, was long left to languish and to struggle through a very feeble existence. You will, therefore, scarcely be prepared to hear that, with all these disadvantages, obstetric medicine and surgery have made more progress and have advanced more rapidly than either of the other departments; and if I prove this, I think you will then admit that I am justified in claiming for it more attention, as well as a higher position, than it has been favoured with as a branch of medical study and practice.

Having said so much, you will naturally ask in what does this progress, or in what do these additions and improvements, consist within the last forty years; and while I am advancing a few facts to sustain my assertion, I am fully conscious that most of the gentlemen I address are as familiar with them as I can possibly be. But, even with all this, a rehearsal may, without any disadvantage, be occasionally indulged in.

Whilst I undertake to direct your attention to the great progress which has been made within the period specified, I shall not be unmindful of the value of your time or of your anxiety to hear the address from the President-Elect. I shall, therefore, confine myself to little more than a syllabus—a mere indication of the work which has been done—and first let me say that we have a more accurate knowledge of menstruation, conception, and generation than was possessed forty years ago. We have more correct views at present of the structure of the ovum—its progress, maturation, and process of expulsion—in other words, the mechanism of

¹ [Dublin Journal of Medical Science, 1881, v71, p269.]

labour, otherwise parturition. We have now a tolerably correct knowledge of the spermatozoon influence, the penetration of the ovule, with a more correct knowledge of the use of the fimbriated extremities of the Fallopian tubes, seizing as they do the ovary, receiving the ovule, by which it is conveyed to the uterus, its nine months' resting place, and during which time it undergoes a wonderful development.

We now possess a knowledge of the true changes which take place in the Graafian follicles. The growth of the embryo in utero has received much attention, and is now tolerably well understood. The characters and the conditions of the decidua uteri occupy different positions now, so that our knowledge here is fixed upon a better basis than formerly. There has been much time and careful research bestowed by Goodsir upon the anatomy, the physiology, and the pathology of the placenta, so that now the uses, the mode of circulation, and the diseases of this organ are tolerably well understood, with much practical advantage to the well-being of both the mother and the child, as well as in regard to the causes of the death of the fœtus in utero, which may be now easily diagnosed and accounted for.

The displacements of the uterus, which have of late received such marked attention at the hands of Hodges, Thomas, Graily Hewitt, &c., are now well understood, and by the means which they have suggested and recommended, can be easily and successfully put right.

Vesico-vaginal fistula, which was at one time the opprobrium of the obstetric art, is now not only in many instances prevented by our better management of labour, but, when unfortunately it does occur, it can, thanks to Marion Sims, be subjected to successful treatment.

The mechanism of labour, so interesting indeed, so fascinating a study in itself, has been placed before us in such a clear and intelligible form by the achievements of Baudelocque, Nægele, and Leishman, that we follow it with care, and take advantage from a knowledge of it in the management of labour.

What shall I venture to say of anæsthetics and their marvellous influences for good in labour, and wherever pain is found to exist? And are we not indebted to Simpson, the great accoucheur, in particular for this magnificent additional resource to our art, and inestimable boon to suffering humanity? I need not dwell on what is so well known to you all—viz., the better management of the different stages of labour which has been effected within the time mentioned.

I do well remember that where cases of placenta prævia were, when met with, much dreaded, now they are faced and treated with self-possession, clearness, and precision, and, as I have shown on a former occasion to this Society, with greater success as regards the life of both the mother and the child.

Long within the time of which we speak, has not the after-treatment of labour undergone a complete meta-

morphosis or change as regards nourishment? Formerly it consisted in starvation, now it is quite the opposite; yet, with all this, I still prefer (though not exactly to the same extreme) offering nourishment in a light form and in a sparing manner for a few days after labour; but I would add that each case must be treated in this respect according to circumstances.

Braxton Hicks' improved method of version by internal and external manipulation—in other words, as it has been called, the bipolar and bimanual mode of version, has been favourably received by the profession, and I have practised it in certain cases with ease to myself and greater safety and advantage at least to the mother.

In the presence of such a number of experts I would be slow to dilate upon the use of the midwifery forceps, or to say more than a word in regard to the increased and increasing use of this instrument.

The more frequent use of the forceps has certainly been the means of relieving the mother from the long, indeed the very protracted, labour from which she was allowed to suffer in former times, but with its earlier use there is greater safety to the life of the mother and her offspring.

The cephalotribe is an instrument of modern invention, and is a valuable addition and improvement upon the old crotchet in bringing away the fœtus with more ease and safety to the mother.

The toxæmic condition has received much consideration by Frerichs, Lever, Simpson, and Braun. But perhaps I should, in introducing this subject, have begun by directing attention to Bright's researches regarding the uræmic origin of puerperal convulsions, or true puerperal eclampsia. Through their labours this very formidable complication of labour is tolerably well understood in its chemico-physiological and pathological characteristics, as well as in its therapeutical requirements.

I can now do but little more than mention the names of some other diseases—viz., phlegmasia dolens, thrombosis, embolism, and, more especially, puerperal fever, as having had of late much more light reflected upon them, and, through them, upon the general puerperal condition.

The last-named disease is now recognised as a form of septicæmia—in other words, this disease is believed to originate with blood-poisoning, and that the poison may be absorbed into the system either from within or from without—that is, either auto-genetically or hetero-genetically. With this disease the study and history of the antiseptic plan of treatment have been very intimately associated, so that the decomposition of the coagula in utero has received marked attention and has led to a knowledge of the influences of septic poisoning and of antiseptic injections.

The use of the speculum, uterine sound, uterine dilator, sponge-tents, laminaria, hydrostatic uterine

Ulster Medical Society
Session 1880–1881
President John Walton Browne

dilators—associated as these instruments are with names of the highest standing in medical science, such as Simpson, Priestley, Barnes, Wilson, and Marion Sims—have been well received, and have introduced a new era in the diagnosis and treatment of uterine diseases.

What shall I say of Spencer Wells and Thomas Keith, who occupy such a prominent position before the profession and the world? for do we not stand in perfect amazement and fascination while we contemplate their magnificent achievements in ovarian diseases and their brilliant successes in ovariectomy—creating as they do a halo around their names while they live, and which will embalm their memories into perpetual spring? May I be allowed to speak of such men as the Brobdignags of medical science, at whose feet we, their Lilliputian brethren, should sit, and, looking up, listen and acquire knowledge and intellectual strength, so as to enable us to grow up into the full stature of the perfect man. Time would fail me to speak of many other important improvements and aids to midwifery as they deserve, such as ergotine, perchloride of iron, bromide of potassium, and chloral hydrate.

The alternative operations for craniotomy should be also here mentioned to show you that this department of our art has not been stationary during the last forty years. These operations are—öophorectomy, hysterotomy, and laparo-elytrotomy.

Although foreign, to some extent, to the subjects under consideration, I had intended expressing a few words on the advantages that we in common with the other branches of medicine have derived practically from the use of the thermometer, the microscope, the aspirator, the spectroscope, the ophthalmoscope, the laryngoscope, and the sphygmograph, which are all instruments of precision, and in the hands of scientific men have yielded some most important and extraordinary results in clinical and pathological investigations. Had time permitted I could have adduced a few facts which would be considered as very striking in the accuracy with which we may by the use of some of these instruments not only diagnose disease, but also distinguish one disease from another; I forbear, however, as I ought rather to apologise for taking up already so much time in “telling you that which you yourselves do know.”

In drawing these hastily written remarks to a close, will you allow me to say that, let the astronomers vaunt their Copernicus, the natural philosophers their Galileo, the mathematicians their Pascal, the geographers their Columbus, we will worship at the shrine of a Hunter or a Harvey. From all that has been stated I think I am justified in the conclusion that “the proper study of mankind is woman.”

I beg to introduce to you Dr. J. W. Browne as President for the year, who, I have no doubt, will try to verify the old dogma—viz., that “doctors differ,” and attempt to prove that the correct rendering is that “the proper study of mankind is man.”

Dr. John W. Browne then read his address.

Paper:¹ Mr. Ex-President and Gentlemen,—A few months since, when from home enjoying a short holiday, the announcement reached me that I had been unanimously selected to fill the Presidential Chair of the Ulster Medical Society for the Session 1880–81. I assure you that although a few of my most intimate friends had spoken to me on the subject, I was quite taken by surprise.

I never for a moment dreamt that upon the 14th November I should be occupying the chair of this honourable and distinguished Society.

At first I hesitated to accept the position, knowing as I do the arduous duties and great responsibility of the office, but on learning that my appointment was really desired by a number of my professional brethren, I felt that I would be wanting in a due appreciation of their kindness if I refused so flattering a compliment; and, gentlemen, I cannot permit this opportunity to pass without giving expression, however brief and faint, to the feeling of gratitude and pride which your unexpected, as unmerited, election of me to the honourable position of your President has inspired—gratitude for the courteous kindness of sincere, but, I fear, too partial friends, and pride that even to them I should have appeared not altogether unworthy of so distinguished a mark of confidence. For myself I could have wished that the duties of the Presidential Chair had devolved upon some member—and you have many such among you—more competent and better qualified than its present occupant to perform them efficiently and satisfactorily. Although I may fall far short of what you may consider the essentials of a President, it will be my constant desire to promote the best interests of the Ulster Medical Society—to endeavour by every worthy means in my power to maintain it in a position worthy of our medical brotherhood of Ulster; but when trying to maintain the position of the Society, I hope that it will never be forgotten that for that support and assistance in the performance of my duties, which I feel conscious of needing, I may ever look to your kindness and forbearance; and from what I know of the several members I will never look in vain.

I cannot hope for one moment to be as successful in the management of the Society as my friend and honoured predecessor, Professor Dill, but, I think, with the aid of the hard-working secretary, Dr. Whitla, I will be able to hand over the Affairs of the Society to my successor in a fairly satisfactory condition; and all I can say, if I fail it will not be from want of good intentions.

When looking back upon the past I consider we have much for congratulation, upon the present state

¹ [Taken from *Transactions of the Ulster Medical Society*, 1880–81, p6 (plain text); and *Dublin Journal of Medical Science*, 1881, v71, p451 (italic text).]

of the Society. We have at last a comfortable reading room, and all the medical papers placed upon the table for the convenience of the members; and we have also the nucleus formed of a modern library. Up to a very few years ago we had few, if any, really good consulting authors added to our collection. We have obtained a fair start, and let us hope that nothing will impede the hands of the officials of the Society in their endeavours to extend the usefulness of the library.

During the session which we have entered upon I hope that every member will determine from the outset to work, and embrace every opportunity of presenting to his brother members—thank goodness we have no sister members—any new fact or facts which may come across his path in practice.

I am one of those individuals who believe that one well-observed fact is worth a thousand theories, and I well remember, a few years since, when studying under my distinguished teacher, Professor Gordon, his teaching was “Observe and note facts.”

To observe in Surgery, or in any other art, a genuine, honest, palpable fact, requires, in my opinion, more strength and force of mind than to spin out any amount of fine theory or plausible hypothesis.

Pardon me for one moment referring to a matter which I consider should be deeply studied by each one of us—I refer to professional ethics. It is not pleasant at any time to have a misunderstanding with a professional brother, but when conflicting opinions and views do arise I consider that all differences should be submitted by both parties to the Council of the Society, and not to the medical brethren at large—so acting would frequently tend to again cement former friends and allay petty jealousies and animosities.

In my opinion that is one of the benefits of being a member of a Society such as ours, where brother meets brother on an equality; and thus, whilst the interchange of thought sharpens our intellects and promotes professional knowledge, it tends to develop a kindly feeling one towards another, and helps to extinguish all professional bickerings; and, gentlemen, why should we wrangle and dispute, are we not all striving towards the same end—the cause, prevention, and treatment of disease? Consider we are but mortals, and remember the shortness of our lives.

It has been written—

“ What is Life? A flower that blows,
Nipp'd by the frost, and quickly dead.
What is Life? The full blown rose
That's scorched at noon and withered.

“ Such is Life—a breath, a span,
A moment quickly gone from thee.
What is Death? Oh! mortal man,
Thy entrance to eternity!”

In thinking over a subject which would be appropriate for an introductory I found myself at a full stop; but I suddenly remembered that my distinguished predecessors, Drs. Wales and Harkin, had, at their inaugural addresses, dealt with special subjects—namely, Dr. Wales, “Use of Stimulants;” and Dr. Harkin, “The Artificial Feeding of Infants.” Both of these addresses were followed by excellent debates, and largely developed latent talent; and it is with the hope that we may have a third discussion that I venture this evening to detain you for a short time upon the anæsthetics—Chloroform and Ether, their Advantages and Disadvantages. I hope also to mention some statistics, and draw your attention to a few of the remedies used to prevent poisoning by chloroform and ether.

Nearly every member of the Society, and especially those engaged in surgical and obstetrical practice, must, to a large extent, use anæsthetics; and I trust that every member will be able to give his experience upon the use of the two anæsthetics.

I may commence by saying that I have a firm and unshaken faith in chloroform, having been present at, or taken part in, its administration hundreds and hundreds of times, and will continue to use it until a more satisfactory anæsthetic is introduced to our notice. The prompt action of chloroform and the calm sleep which it induces, its pleasant odour and taste, and the usual absence of subsequent vomiting, if care be taken in dieting the patient, would be alone sufficient to secure its general adoption were it not that so many physicians and surgeons regard it as uncertain and dangerous. With some the conviction is so decided that they advocate its entire disuse as the only radical method of avoiding the attendant risks.

I am quite cognisant of the fact that certain medical journals have denounced the use of chloroform and highly approve of the use of ether. And one recent writer went so far as to say that—“A surgeon who used chloroform in preference to ether, should a death occur in his practice, deserved to be tried for manslaughter.”

The medical journals still continue to report a noticeable number of fatal cases of chloroform poisoning, and these are occasionally referred to by the editors with stringent comments. According to one statement a death occurs in every 2,723 administrations of chloroform, while a more recent writer, Mr. B. Carter, in *The Lancet*, August 7th, 1875, gives the proportion as 1 in 2,500 patients; and Mr. Carter goes on, in the same paper, to state that ether is in all respects as available and as effectual as chloroform, and that it is absolutely safe. He says: “I do not believe that it has ever destroyed life, nor do I believe it has any tendency to destroy life.”

I fear Mr. Carter is a prejudiced writer; other men are as competent to form an opinion as he. Further on I shall show ether is considered unsafe by certain writers, especially so in children. In *The British Medical Journal* 6th November, 1880, you can read a letter

from Mr. Jonathan Hutchinson, advocating the use of ether in preference to chloroform, and calling upon the editor to continue his advocacy until ether is universally used in all suitable cases.

You see Mr. Hutchinson uses the words “suitable cases,” admitting there are some patients who take chloroform better than ether. He prefers to administer chloroform to old people and young children. With all due respect to Mr. Hutchinson’s opinion, were I to give ether at all it would be to old people owing to its recognised stimulating effect upon the heart. In the same journal Mr. Hutchinson’s letter is followed by one from Mr. Jacob, of Leeds, also advocating the use of ether; but admitting that there are certain dangers attendant upon the administration of that anæsthetic. Immediately succeeding Mr. Jacob’s letter is one from the administrator of anæsthetics at the Victoria Hospital for Children.

He considers that in all inquiries relating to the respective merits of the two anæsthetics, chloroform has always been heavily handicapped; and submits that if ether or chloroform were given in cases of similar degree of risk, the mortality of the two would be found to be very much on a par.

Notwithstanding all the adverse opinions and writings, yet physicians and surgeons will rely upon their individual experiences. One has used chloroform in hundreds of cases without any bad results, and considers it safe and reliable; another had almost adopted the same conclusion after a long experience, when alarming symptoms or a fatal issue occurred in his own practice and shook his confidence. Still another has been alarmed by apparently dangerous phenomena resulting from ether, and has returned to chloroform with the idea that its danger has been exaggerated.

It is very odd that the first attack upon chloroform as an anæsthetic was made in America, the birthplace of ether; and all of you must have observed that in the many discussions upon the merits of the two anæsthetics nationality has entered largely into the debate—America v. England; and from the visit of Dr. Joy Jeffries, of Boston, to this country, in 1872, must we date the peculiar ether craze which has sized the minds of some men. It is very remarkable that many of the fatal cases of death from chloroform inhalation have occurred in the practice of dental surgeons, private practice, or in some small institutions—a circumstance which would seem to show that there had been some fault in the mode of administration. A writer in *The British Medical Journal*, January 1st, 1876, claims:—“That by proper care chloroform is a sufficiently manageable and safe agent for use, and that it is not the chloroform which is to blame, but the mode of administration.” With this opinion I fully concur. I always feel safe during an operation when the experienced house-surgeon is looking after the anæsthetic; and I must confess when an inexperienced person is locum-tenens

I always feel uneasy until the operation is finished. I suppose many of you have read of a death from chloroform at one of the London hospitals? Just before the administration the house-surgeon was summoned to a coroner’s court and was consequently absent during the operation; death occurred. Another death from chloroform has also been reported, where the experienced chloroformist was unavoidably absent during the administration. Here you see in the one case the experienced house-surgeon absent, in the other case the chloroformist otherwise employed; the chloroform may or may not have been administered by an experienced person. Comment is unnecessary; still they are deaths from chloroform.

Now let us consider some of the advantages and disadvantages of ether and chloroform.

Advantages of Chloroform.—In most cases its administration is agreeable to the patient; rapid in its action; complete insensibility produced; the entire absence of excitement when the insensibility is complete; little laryngeal or bronchial irritation; the easy maintenance of the anæsthetic influence, and less liability to cause vomiting.

Disadvantage is said to be the risk attending its administration. Death from the inhalation of chloroform may result, and probably does often result, from gradual paralysis of the respiratory muscles from the effects of the chloroform upon the respiratory centres.

There is another form of death from chloroform—cardiac syncope—the heart at one moment beating well, and the next moment stops. So you see chloroform may cause death not only by arresting respiration, also by its depressing action on the heart—this action on the heart being in my opinion, the greatest disadvantage of chloroform, because when the respiratory centres are affected we can watch the change of breathing from its comparatively calm state, gradually becoming more shallow and stertorous; here by following out certain rules danger can be averted. But when death takes place from cardiac syncope, here there is no warning, the time between life and death being almost absent; so that, granting this cardiac syncope to be a serious disadvantage to the use of chloroform, we must take every precaution, before commencing the administration, to limit the risk, by placing the patient in the recumbent posture, and attending to the other well-known details.

Advantages of Ether.—It is said that all records show it to be safer than chloroform—that is a matter of opinion. To my mind the greatest advantage of ether over chloroform which can be presented is, that although ether, like chloroform, may kill by arresting respiration, it does not destroy life by its depressing action on the heart—i.e., it does not kill by cardiac syncope.

Disadvantages of Ether.—It is an unpleasant anæsthetic; it requires a long time to effect complete unconsciousness. The time required to get the full effect of the ether varies to a far greater extent with different people

than in the case of chloroform. As a rule, it is twice as long, the quantity requiring to be inhaled being much greater. Other disadvantages are the restless excitement that often results from its administration, very different to the extreme quiet of chloroform unconsciousness; also the danger of ether vapour catching fire should any light be placed incautiously near the patient's mouth during inhalation. Dr. Neligan mentions, as one of the disadvantages, the persistent taste and odour experienced even for days by those to whom it has been administered; and Mr. Clover has drawn attention to the fact that the flow of saliva is considerably increased during the administration of ether and occasionally gives trouble.

Is Ether really Safer than Chloroform?—If we are to believe all that has been written on the point I believe that we must come to the conclusion that ether is the safer of the two anæsthetics; but, gentlemen, it is to obtain your individual opinions that I have introduced the subject. We still find many medical men very much in favour of chloroform, notwithstanding what has been written in opposition to it. I think we must all come to the conclusion that for operations upon young children and pregnant women chloroform is to be preferred to ether.

A few years since Dr. Tripier, of Paris, read a paper before the French Association for the Advancement of Science, and related cases in which the administration of ether to young children for surgical operations was attended by an arrest of respiration, and alarming symptoms ensued. Dr. Tripier instituted experiments upon young cats with ether, and found, as in young human subjects, an arrest of respiration often occurred. Older animals were less liable to the accident. He, therefore, considers anæsthesia by ether in young subjects as dangerous, and that chloroform for them should be preferred.

My opinion is that ether does not hold so good a position in the scale of safety as it did a very few years ago. I remember some six years since nothing but ether was administered at several English and Irish hospitals I visited, and I was very much surprised to find three weeks since, whilst revisiting these hospitals, either chloroform in use or a mixture of ether and chloroform. I dare say you are aware that up to 1872 Mr. Spencer Wells used ether largely, and that he now either uses chloroform or bichloride of methylene. At the Samaritan Hospital for Women, London, I had the pleasure and advantage of seeing a few ovariectomies performed. Here the anæsthetic used was chloroform administered by Junker's inhaler; and from conversations I had with several medical men just returned from the great medical schools of the Continent, I learned chloroform is the anæsthetic chiefly used.

"In Germany chloroform has a less disputed sway than in any other country, and is now, according to Dr. Kappeler, of Germany, so far as he knows, exclusively

used. In Austria the course pursued by Billroth is an index of the lack of full satisfaction with either ether or chloroform."¹ He is an advocate of, and constantly uses, a mixture consisting of three parts of chloroform, one part of ether, and one part of alcohol. This is the mixture which was so strongly recommended by the Committee of the Medico-Chirurgical Society.

Even in certain parts of America—the birthplace of ether—and notably in the Southern States, chloroform is preferred to ether. A paper bearing out this statement has lately appeared, written by Dr. Chisholm, of Baltimore.² This confidence in chloroform seems to be based upon the experience of surgeons with it in the Confederate Army, and in the Northern States the warmest advocates are surgeons who have had large experience during the American War. According to Sedillot and Malgaigne, ether has never succeeded in supplanting chloroform in France. Gross, of Philadelphia, prefers chloroform.

Why, gentlemen, have such men as Spencer Wells, Bantock, Billroth, Gross, and others, given up the use of ether, and adopted either chloroform or a mixture of chloroform and ether?

In Scotland, as we should naturally expect, chloroform is the anæsthetic in common use, and has a strong advocate in Professor M'Leod, of the Glasgow University. Dr. M'Leod, in *The British Medical Journal*, January 1st, 1876, lays down some excellent rules regarding the administration of chloroform, and goes on to state:—"He believes a good many of the deaths under chloroform have apparently been due to patients, suffering from heart disease, not being completely insensible when the operation was performed, and the shock killing them. Here," he says, "the chloroform is blamed, whereas what was really wrong was that it was not sufficiently pushed." He also states he never measures the amount of chloroform poured on the sponge or towel, simply watching the effects, and considers more deaths are due to too little than to too much chloroform being given. In his paper he alludes to a very important point—namely, always to administer the chloroform in the recumbent posture. With this opinion I think we must all agree, as you are aware a large proportion of the deaths from chloroform have occurred in the practice of dentistry, and chloroform is generally administered by dentists when the patient is in the sitting posture.

Bearing out Dr. McLeod's opinion regarding the shock killing the patient, not the chloroform, a letter has just appeared in *The British Medical Journal* by an Edinburgh professor. When speaking of the sudden arrest of the heart's action from reflex irritation during an operation, he says:—"The treatment of the sudden arrest of the heart's action from reflex irritation should consist in boldly pushing the administration of the

¹ *American Journal of Medical Sciences*. July, 1880.

² *American Journal of Medical Sciences*.

chloroform, in the hope that relaxation of the spasmodic contraction of the heart will speedily occur.” My idea is that chloroform is perfectly safe when administered with the precautions advocated by the Chloroform Committee of the Medico-Chirurgical Society in 1864, and, in addition, carefully adhering to the rule always to administer the anæsthetic in the recumbent posture.

The relative advantages of ether and chloroform were carefully investigated by the Committee on Chloroform appointed by the Medico-Chirurgical Society (Lancet, July, 1868). In their Report they state that ether is slow and uncertain in its action, though it is capable of producing the requisite insensibility, and less dangerous in its action than chloroform. In many respects the action of ether is the same as dilute chloroform. The primary stimulating effect of ether on the heart’s action is greater and of longer duration, and the subsequent depression of the heart’s action is not so great as that produced at the same degree of insensibility by chloroform.

On the whole, however, the Committee concur in the general opinion which in Great Britain has led to the disuse of ether as an inconvenient anæsthetic. The Committee found a mixture of ether and chloroform to be as effective as pure chloroform. This Report was written in 1868, and it was in 1872, subsequent to the visit of Dr. Jeffries to this country, that ether suddenly came into vogue. The Committee suggested for use a mixture composed of chloroform two parts, ether three parts, and alcohol one part, on the ground that ether and chloroform blend uniformly when combined with alcohol, and the constituents escape equally in vapour. The mixture of ether and chloroform I have lately seen used with good effect; the mixture is now used at the London Ophthalmic Hospital—not ether alone.

I now wish to introduce a few words relative to the statistics of the administration of the two anæsthetics. Some deaths have, no doubt, occurred at Guy’s Hospital, London, during the administration of chloroform, but here it was given 12,000 times before any serious accident occurred. In the Crimean War it was given 25,000 times without a death, and during the American War 7 deaths occurred with 120,000 administrations. Professor Andrews, of Chicago, in 1870, collected from the different American and European hospitals the statistics of 117,078 cases in which chloroform was used, with 43 deaths. Of 92,815 cases of etherisation 4 died, and a mixture of chloroform and ether was employed in 11,176 cases with 2 deaths. Professor Gross, of Philadelphia, has given it upwards of 8,000 times without a death. Syme gave it about 6,000 times without any serious occurrence, and Professor Simpson is said to have met with but one death in all his immense experience. Professor Nussbaum, of Bavaria, in upwards of 15,000 administrations, never lost a patient; Billroth has given it successfully upon 12,500 occasions. It is calculated it has been administered in Belfast, includ-

ing hospital and private practice, upwards of 7,000 times; and up to the present, I am happy to say, no death has occurred. Long may we have this story to tell.

It is extremely odd that no writer has made any attempt to present the total number of deaths which have occurred under ether. This death-rate is a very important matter when chloroform is under consideration, but of no consequence in regard to ether. Still, Turnbull in America, Kappeler in Germany, Perrin and Lallemand in France, have reported not a few deaths resulting from the inhalation of ether (see American Journal of Medical Science, July, 1880). Kappeler gives a class of deaths occurring after the administration of the ether is over, and refers to the investigations of Lallemand, Perrin, and Duroy, showing that ether is retained a longer time in the organism, and has therefore a decidedly more prolonged operation. As regards the deaths from ether Dr. Kappeler says:¹—“We are as little prepared to state in figures the dangers of ether as those of chloroform, since neither the number of deaths from it nor the number of administrations are known, and the attempts made to state the proportion of deaths to administrations are mostly the product of the bitter contest—ether versus chloroform.”

From these favourable reports and statistics, which I have just read, I think we may conclude that the time has not yet come when chloroform will be laid aside; and I believe its use will continue so long as there is the existing diversity of opinions regarding its merits. Hence it must be now, as it has been, the earnest wish of surgeons and physicians to diminish the attendant danger; and this leads me to speak of a few of the more prominent remedial measures and preventions to nullify ether and chloroform poisoning.

In threatened death from chloroform the means which we most frequently rely upon are—(1) Drawing forwards the tongue with tongue-forceps; this method was first introduced by Mr. Lister, but it is now considered you gain more by drawing forwards the inferior maxilla; by so doing the muscles which connect the lower jaw with the larynx and os hyoides are drawn upon and open the larynx; it is said you gain a freer opening of the larynx by this method; at the same time as you draw forward the tongue or lower jaw it is recommended to place the patient upon his left side, (2) Nélaton’s plan.²—Inverting the patient so as to lower the head and determine a flow of blood to the brain. (3) Artificial respiration, by Sylvester’s, Marshall Hall’s, or Howard’s methods.—When practising artificial respiration you can place a sponge saturated with hot water over the heart. This is recommended by Dr. M’Leod, of Glasgow.

In threatened collapse from chloroform, and when the heart’s action flags, ether has been injected hypodermi-

¹ American Journal of Medical Science. July, 1880.

² The late Mr. S. M. Bradley, of Manchester, has reported cases treated successfully by this plan.

cally with marked success. Lately Dr. Moinet, of Edinburgh, has spoken highly of the subcutaneous injection of digitaline as a cardiac stimulant in conjunction with artificial respiration. The galvanic battery is also occasionally used to avert impending danger; but those of you who have been reading *The British Medical Journal* lately must have noticed a letter from Professor Schafer, of University College, on the action of the galvanic current when applied to the cardiac region. He says:—"The effect of direct stimulation of the heart is so opposite, according to the part which happens to be brought under the direct influence of the excitation, that it is no exaggeration to say that the treatment is at least as likely to arrest a beating heart as to set an inhibited one in activity." So that, taking into account this celebrated physiologist's experiments, I consider we must not rely too much on galvanism.

In this recent letter you will also observe that Professor Schafer speaks very highly of a hypodermic injection of atropine in all cases in which chloroform is about to be administered. He states that it is well known that atropine paralyses the cardiac inhibitory apparatus, and since it is probable that death in these and similar cases results from a stimulation of this apparatus, either directly by the drug, or it may be, in some instances, in a reflex manner, by the stimulation of abnormally excitable afferent nerves during the actual performance of the operation, there seems good reason for the employment of atropine. He has also performed a number of unpublished experiments to prove the value of atropine as an antidote to the cardio-inhibitory effects of chloroform; and he is of the opinion that atropine should be injected subcutaneously in all cases of anæsthesia by chloroform as a preventive. As regards the previous subcutaneous injection, a letter has just appeared in *The British Medical Journal*, written by Dr. Muro, of Manchester, speaking of the beneficial effects of the atropine injection in chloroform inhalation. He has also performed a number of experiments, which he states he forwarded to the Committee of the British Medical Association, but they did not publish the results of his experiments for reasons best known to themselves.

Dr. Muro is of the opinion that atropine administered previously to the giving of chloroform is a powerful heart protector, making it impossible for the latter to kill, even when administered with that intention.

The modification of the ordinary course of chloroform anæsthesia by the preliminary injection of morphia deserves attention. This is known by the name of the "mixed narcosis," and was first resorted to by Professor Nussbaum, of Bavaria. It is claimed for the "mixed narcosis" that it is especially adapted to prolonged operations, rendering a far less quantity of chloroform necessary—the anæsthesia being continued with far less repetition of inhalation; that the stage of excitement is lessened, and that thereby the dangers of anæ-

sthesia are diminished. It is recommended to make the hypodermic injection of one quarter grain of morphia twenty minutes before administering the anæsthetic, because if made immediately preceding the use of the anæsthetic the stage of excitement is increased.

In *The Lancet* of December, 1877, you can see papers upon the "mixed narcosis method," and details of operations performed by Mr. Marshall and Dr. Sidney Ringer. Mr. friend, Dr. J. F. Wales, informs me that this method is frequently resorted to at the Leeds Infirmary. It appears that none of the advantages of chloroform-morphia attach to ether-morphia narcosis.

Dr. Kappeler¹ gives his experience with twenty-five cases, and states that the combination of these two agents is rather injurious than beneficial.

The medicinal agent which seems to promise most as an antidote to chloroform and ether poisoning is the nitrite of amyl, since physiological experiments have developed an antagonism between the effects of nitrite of amyl and chloroform.

While chloroform impairs reflex excitability and produces contraction of the cerebral vessels, nitrite of amyl restores this excitability and causes their dilatation. Into the enlarged vessels the blood freely enters, and a rapid circulation follows.

Mr. Bader, Ophthalmic Surgeon to Guy's Hospital, in *The Lancet*, May, 1875, gives the results of his experience with the nitrite of amyl. He says:—"In three or four minutes after taking three drops of nitrite on sugar, the blood-vessels of the retina, especially the veins, become enormously dilated and gorged with blood, leaving no doubt as to the simultaneously existing cerebral hyperæmia with increased circulation of blood."

He further says:—"The most striking effects of the nitrite were the quick restoration of breathing, a good colour, and the rapid appearance of sickness."

As to the essential mechanism of this, Dr. Robert Pick (*British Medical Journal*, February 26, 1870) considers that the following conclusions are established by recent experience:—

1. Amyl nitrite produces a direct paralysis of the vascular wall.

2. The effect of the drug must be peripheral; but whether the smooth muscles themselves, or the terminal ends of nerves in these, or, finally, certain hypothetical peripheral ganglionic cells, are the points of attack, is unknown.

Dr. William Dabney, in the "Transactions of the Medical Society of Virginia, America," reports a series of experiments upon cats and dogs, showing the value of nitrite of amyl in cases of threatened death from chloroform and ether.

Dr. M. Schüler has written in *The Berlin Clinical Journal* a series of experiments performed with the

¹ *American Journal of Medical Sciences.*

nitrite upon rabbits. He removed a small portion of the skull, leaving the *dura mater* intact. He found, when chloroform was inhaled for a short time, a diminution of size of the arteries of the *pia mater*, then of the veins, took place. This is accompanied by a corresponding decrease in the pulsations. Soon follows an increasing relaxation of arteries and veins, and at last marked venous stasis. As a result of the venous condition of the blood, the arteries become speedily of a darker hue.

The inhalation of the nitrite of amyl promptly removes the effects of chloroform on the vessels of the *pia mater*. The arteries dilate and become of a bright colour, the veins become of a clearer hue, and the respiration which had been embarrassed grows easier and more frequent. He also states that the reflex excitability which has been destroyed by chloroform narcosis is soon fully re-established under the influence of the nitrite of amyl.

I think these experiments show that in nitrite of amyl we have an agent which will prove of great service when disagreeable symptoms show themselves during the administration of chloroform and ether.

I have thus, gentlemen, in a feeble manner endeavoured to put before you a few practical observations regarding two very important anæsthetics. I had originally intended taking up the subject of anæsthetics in general, and introducing to your notice bichloride of methylene and the two new agents—dichloride of ethidene and bromide of ethyl; but I feared the paper would be too long, and I feel certain your patience is already exhausted.

Annual dinner was decided to be held on the 23rd instant Tuesday on the motion of Dr. Esler. Moved and seconded and passed that the President, Professor Dill, Dr. Harkin, Dr. Moore and Dr. Whitla be appointed Dinner Committee.

James Moore M.D., Chairman
7th December 1880

The Second Meeting Session 1880–1881 was held upon December 7th 1880.

Present, Dr. James Moore (in the chair), Dr. Fagan, Drs. Kevin, McHarry, Anderson, Dempsey, Workman, Whitla, Smyth (Royal Hospital), Professor Dill, Dr. J. W. Browne (who came in late), and several students.

Dr. Haslett was elected a member of the Society.

Dr. Smyth, House Surgeon Royal Hospital, was proposed by Dr. Whitla and seconded by Dr. Fagan as a member of the Society.

Dr. R. J. Anderson read a paper upon the embryology of the lingual muscles.

Upon the motion of Dr. Dempsey seconded by the Secretary the discussion upon the paper was postponed.

Dr. Fagan opened the debate upon ether and chloroform which was freely entered into by most of those

present.

Paper:¹ MR. FAGAN said:—Mr. President,—It is unfortunate that the discussion on the important matter that formed the subject of your Inaugural Address should have been so long deferred. I dare say there are some members of the Society who feel, as I do, that very many important points touched on by you have escaped their memory; while the general impression remains that your exhaustive résumé of the literature of the subject has left one very little virgin ground to work on. As well as I can remember, the drift of your arguments led to the conclusion that chloroform, although not devoid of danger, possessed advantages over ether that would justify you in still adhering to it till a safer and more effectual anæsthetic be discovered.

Granted that I am right in quoting this as the expression of your opinion, I am not astonished at your entertaining it. As you state, I think, in your address, chloroform has been given in Belfast 8,000 times, from its discovery up to the present, without mishap attending it. You have had a large experience, and a pleasant one, of its administration; and it is but right to think that so old, so tried a friend, that has ever proved effectual, and never dangerous in your hands, should not be hastily thrown aside, to be supplanted by another more capricious in its action, less effectual, and acknowledged by many to be not entirely devoid of danger. But, while influenced by the same feelings towards the favourite anæsthetic, I cannot altogether turn a deaf ear to the repeated sounds of warning lately rung out to us through our leading medical journals and by some of our most eminent professional confrères. One of our most influential journals has more than once, in its editorial pages, warned its readers of the serious responsibility that rests on those who continue to employ chloroform in preference to ether; and this sentiment is endorsed by one of the highest authorities in our profession, in the following words, addressed to the editor:—"Will you allow me to express an earnest hope that you will continue that advocacy as long as necessary—that is, until ether is universally employed in all suitable cases." And, again, the same weighty authority says:—"I should consider myself very culpable if I ever permitted the use of chloroform, except in certain cases. I can testify in the strongest possible terms to my own feeling of security with the one and of risk with the other."

Having heard the opinion of such a weighty authority, backed up as it is by numerous correspondents of more or less professional status, are we to consider the case closed, and chloroform condemned either to expulsion from, or to a very obscure corner of, the surgical armamentary? I should be sorry to think so. I believe it will long remain a trustworthy friend both to the anxious surgeon and the suffering patient, and, as the

¹ [Dublin Journal of Medical Science, 1881, v71, p558.]

reserve force in the array of anæsthetics, may be called up with confidence when the more favoured ones have failed. It is by such an address as yours, Mr. President, that the merits and demerits of both ether and chloroform will be clearly exposed, and in this way, tested by the light of facts, its proper position will be assigned to each. Let me here define the limits I intend to go to in treating this subject, which, you will allow, is a vast one. The all-important question for us to decide on is—What anæsthetic is the most potent, and at the same time the most free from danger; and as chloroform and ether are, I may say, universally acknowledged to possess these characters more so than any others, I propose to confine myself to a consideration of their relative advantages and dangers.

It may be fairly asked what light can I throw on the subject whose short experience is based on comparatively few cases. In reply to that I may say, I will add my quota to that of others, while I may be permitted to examine ascertained facts by the light of such accumulated experience, and so will satisfy myself, if not others, as to the relative merits of both anæsthetics, and shape my line of action in accordance with the opinion I form. By each of us acting thus, extreme views may be got to harmonise, conflicting opinions to tone down, and we may be free from such damaging advocates of either form of anæsthetic as the correspondent who lately, in one of the journals, hoped that the general feeling of the profession with regard to the use of chloroform would be like that of a medical friend of his who, when asked to give chloroform, said, “He was leaving town next day, and did not want to be detained by a coroner’s inquest, but would give ether if agreeable.”

Where are we to look for data from which to draw a safe conclusion? We must first look to the recorded experience of the advocates of both ether and chloroform in the old and the new worlds, for in both each has had, and has still, its warm defenders. Let us first take chloroform and see what experience has to say in its defence as regards its safety.

In our own country Syme administered it in 5,000 cases without a death; he expressed his opinion on this subject in a very laconic manner—“A case for operation is a case for chloroform.” Mr. Lister maintains that deaths from chloroform arise from an overdose and from too long-continued administration. In Germany Nussbaum records 15,000 cases, and Billroth 12,500, and no death. Dr. M’Guire, in America, 15,000 cases and one death; and, during the civil war, 11,500 cases and one death.

In the French army, in the Crimea, it was administered in 20,000 cases without a death. In our own hospital chloroform has been administered in 6,000 cases and no death. Then, again, there are other hospitals where there has been one death in 520 administrations. Since 1875, the following list of deaths from chloroform

have been reported to the leading Medical Journals of this country:—

1876, 10 deaths.	1878, 13 deaths.
1877, 12 „	1879, 8 „
And during the first 10 months of 1880, 20 deaths.	

The relative number of deaths to the cases of administration can only serve as indications and approximations, but can never be relied on with any degree of accuracy. Richardson estimates one death in every 2,500 administrations.

Many extenuating circumstances have been brought forward by the advocates of chloroform to lessen the effect of this large mortality—such as self-administration; administration by ignorant and careless persons; cases of death from fright; according to Mr. Lister, an overdose from too long-continued administration; Billroth’s theory of peculiar idiosyncrasy; mechanical causes, as death from collection of mucus in the larynx and air-passages; and impure chloroform. This plausible theory may suit such ardent advocates as those who teach with Sédillot that, “le chloroform pur, et bien employé ne tue jamais.”

If the ratio of deaths from chloroform to administrations is only known approximately, even this is lacking in regard to ether, and as regard to figures, they are no better than guess-work. In a late treatise on anæsthetics a comparison of the two was attempted, and this conclusion was arrived at—that three deaths occurred from ether during the first fifteen years of its use, and 77 from chloroform during the first fourteen years of its use; and during the first year ether was used there was 1 death, and during the first year chloroform was used, 9.

Let us now listen to the statement of Dr. Turnbull:—In the city of Philadelphia alone ether has been used, with but one exception, since its introduction in 1846 up to the year 1878, without a single primary death, and only one recorded secondary death. General testimony of this kind, the record of frequent deaths from chloroform, the tone of the Medical Journals, together with the decided opinions of many leaders in our profession, show that the lesson can be learned from facts quite as well as from figures; and I feel that that lesson teaches us that chloroform is a far more dangerous agent than ether.

Let us now consider what experiment has to add to experience concerning the action of these two anæsthetics on the system. It is conceded, I believe, that the great source of danger in the use of anæsthetics is their influence on both the circulatory and respiratory nervous centres. The most reliable information on this point is to be obtained in the report of the Scientific Grants Committee of the British Medical Association. I will quote one or two sentences from that report that will speak for themselves. Having described the mode by

which the animal was subjected to the experiment, it goes on to say—"It soon became apparent that when chloroform is given in this way there is at once a most serious effect on the heart; the right ventricle almost immediately begins to distend, and the heart presently stops, with the right ventricle engorged with blood. The heart had often, in the case of rabbits, virtually come to a stand-still within a minute of the introduction of chloroform by the method described.

The contrast was most striking when ether was used instead of chloroform. Ether may be given for an indefinite period without interfering with the heart. We kept artificial respiration with ether in the circuit for an hour, not including twenty minutes occupied in producing anæsthesia, and at the end of that time the exposed heart was beating as vigorously as at first."

That chloroform injuriously affects the respiratory centre is also the opinion of this committee, and they account for it in this way—there is failure of the heart in the first instance, and the insufficiency of its subsequent pulsations caused the failure of respiration. In such a state of the circulation the respiratory centres would probably be insufficiently supplied with blood, and be consequently liable to cease acting. Can it be wondered at, that, looking at this subject both by the light of experience and experiment, the advocates of ether should be so loud in its praises and strong in their denunciation of chloroform.

May I be permitted to give my own limited experience of these two agents; and, first, as regards ether, I believe I have been the first to administer it in Belfast in a systematic manner. I have used it in the Children's Hospital for a period of five years, in the cases of children ranging between two and fourteen years of age. It took a very long time to produce anæsthesia, the struggling was sometimes painful to witness, and it was usually accompanied or followed by vomiting, besides being very disagreeable to the administrator. In some cases complete anæsthesia could not be produced, and in rare cases it had scarcely any effect.

As weighing against these disadvantages was the great security I felt as regards the safety of the patient. This was always indicated by the good colour of the face, and steady, full beat of pulse. In one case (a private one) of amputation I gave 8 ozs. ether with scarcely any effect, and had in the end to use chloroform, which at once proved effectual.

My experience of chloroform is greater than that of ether, and although I have never been so unfortunate as to witness a death from it, I have, on many occasions, seen alarming symptoms in my own cases as well as in those of other surgeons.

Before concluding, I will make some general statements, the truth of which, I think, is acknowledged on all sides:—1, that chloroform has never been fatal in cases of parturition; 2, that the deaths from it are almost nil in military surgery; 3, that the large majority

of the fatal cases reported are those where it was administered for minor operations and operations of expediency; and, 4, that there was culpable carelessness and ignorance on the part of those who administered it in many of the fatal cases reported.

As regards ether:—1, it is not devoid of danger to life per se; 2, it is unpleasant, and difficult to administer, and has a great many drawbacks in this way that chloroform has not; and, 3, it is a far less potent anæsthetic.

Dr. Kappeler, in his essay on Billroth's system of surgery says—"The assumption of physiologists that the surgeon is responsible for death from ether, in contradistinction to chloroform, and that death from ether may always be avoided by precaution, stands, in my opinion, without any foundation whatever.

From the experience of the operating table it cannot yet be maintained with absolute positiveness that the administration of ether as an anæsthetic has a considerably less amount of danger than chloroform. We are as little prepared to state in figures the dangers of ether as those of chloroform, since neither the number of deaths from it nor the number of administrations are known, and the few attempts made to state the proportion of deaths to administrations are mostly the product of the bitter contests, 'ether versus chloroform,' and the necessary impartiality is lacking."

The conclusions that I have arrived at from the several considerations of the subject are—

1. That ether, although a less potent, is a safer anæsthetic than chloroform.
2. That ether should be administered in all cases where the circumstances will permit.
3. That chloroform should not be used in minor operations, or operations of expediency.
4. That every precaution should be taken beforehand against the supervention of dangerous symptoms, and that every requisite for combating such symptoms should be in readiness for immediate use.

Third Meeting Session 1880–1881.

Present, Dr. J. W. Browne (President), Dr. Dill Ex-President, Dr. Fagan, Dr. McConnell, Dr. John Moore, Dempsey, Kevin, Workman, Esler, Mackenzie and Whitla.

Dr. J. Smyth, House Surgeon Royal Hospital, was elected member of the Society.

Dr. John Moore showed a large uterine tumour which he removed during labour.

Dr. Whitla exhibited a calculus which he removed from a girl 2 years old.

Dr. J. Browne President exhibited some interesting specimens and read notes of a case requiring recurrent amputation of the thigh.

J. Walton Browne

Fourth Meeting 1880–1881 was held January 4th 1881 Tuesday 8 p.m.

Present, Dr. J. W. Browne President in the chair, Professor Dill, Professor Gordon, Drs. O'Neill, Wadsworth, Haslett, Smyth (H. S. Royal Hospital), McHarry, Esler, Dempsey, Fagan, Kevin, Dr. James Moore, McConnell, Whitla, and a very large attendance of students.

Dr. Whitla proposed and the President seconded the nomination of the following members: Dr. McCaw, Dr. Gilmore, Dr. Stewart.

Mr. Fagan read a paper upon a case of head injury and showed the parts involved.

Professor Gordon submitted a paper on intracapsular [fracture] of the head of the femur and exhibited a large number of specimens.

Paper:¹ *If we carefully compare the statements usually promulgated by surgical writers with those which may be deduced from a good collection of fractures, whether intra- or extra-capsular, it will be at once apparent that much information is still wanting to bring them into perfect accord. The object I have in view in bringing forward the present communication is to show that we have still something to learn regarding these common accidents.*

I shall first take up the Intra-Capsular.

The specimens which I now exhibit clearly demonstrate that we have three forms of this accident, and I might add a fourth, but it might be justly regarded as a variety of the ordinary Intra-Capsular Fracture, in which the compact tissue of the inner surface of the outer fragment has been driven into the inner fragment, forming an impacted intra-capsular fracture.

FIRST SPECIES.

Transverse Fracture of the Neck of the Femur through its junction with the Head, without Laceration of the Periosteum—Osseous Union.—I met with my first specimen of this rare form of accident in 1848, and after careful examination I came to regard it then, as I do now, as an example of a species of fracture hitherto over-looked, or at least not recognised as a special form.

The head is displaced or rotated backwards, and is slightly penetrated by the neck behind, whilst in front the margin or corona of the head and the anterior surface of the neck are on the same plane. In one of the specimens the neck is two or three lines in advance of the head.

The extent to which the head is rotated backwards ranges in the different specimens from 25° to 35°, as is shown by the altered aspect of the depression for the attachment of the ligamentum teres. There is osseous union in all of them.

In 1871 I obtained a similar specimen, in which there was also firm osseous union. During the following session I met with a recent example in the anatomical rooms. In this specimen the head could be moved

slightly in any direction, the sole bond of union between it and the neck being the untorn periosteum. These three specimens are deposited in the Queen's College Museum, and, when carefully considered, show clearly that an aged female, probably bedridden, may sustain fracture of the neck of the femur from some slight motion, which may be unattended by any shortening or other evidence of the accident, except perhaps inability to move the limb, with pain on pressure in the groin below the margin of the acetabulum. When a limb dangles uselessly from the pelvis, owing to any cause, such as paralysis or scrofulous disease of the knee-joint, the neck and head of the femur become more vertical—i.e., the angle between them and the shaft becomes more obtuse, and the head becomes displaced upwards and outwards, so as to project over the upper surface of the neck.

In such a condition the compact tissue is unusually bent as it passes from the upper border of the neck to the head. This form of displacement can be easily recognised by the continuity of the upper surface of the neck with that of the head. The displacement noticed in these cases differs in direction from that which occurs in these fractures, as in the latter the fossa of the ligamentum teres looks unnaturally backwards, in the former upwards.

In point of fact, I do not know of any cause that would produce displacement backwards of the head except fracture, and that this view of the matter is the correct one, a specimen recently produced leaves no room for doubt. The three specimens are similar in size, they are in a state of atrophy, and the deformity in each case is doubtless the result of fracture. In cases of this kind the periosteum is untorn, the fragments, if the patient remains quiet, are held closely in apposition, and an ample supply of blood is afforded by vessels of the periosteum and ligamentum teres, so that the conditions which prevent osseous union in the ordinary intra-capsular fractures do not exist here.

Treatment.—In the treatment of these, as of other fractures of the neck of the femur, I am opposed to the use of splints. If a splint be applied, it loads the limb unnaturally, and compels the patient to maintain the supine position. The back becoming painful, the patient tries to procure relief, but the limb being loaded by the weight of the splints, more than usual exertion is necessary to alter the position, which acts chiefly on the broken surfaces; whereas, if the limb is free, the patient changes the position slowly, without disturbing the fragments or causing them to grate forcibly upon each other. In addition to this may be noticed the injurious effects on aged persons of prolonged maintenance of the supine position. I have no doubt that the mortality is much greater in cases where splints are used than in those where they are not.

SECOND SPECIES.

Transverse Fracture in the Middle of the Neck of the

¹ [Dublin Journal of Medical Science, 1881, v71, p97.]

Femur, with Osseous Union.—There are six specimens of this fracture in the Museum of the Queen's College. They are all so much alike that the description of one would apply equally to all the others. When force is applied from before backwards, the neck being in a state of extreme senile atrophy, it bends and breaks, forming a salient angle in front, and an acute concavity behind. The periosteum being untorn, osseous union takes place, resembling the Greenstick fracture which occurs in young persons, and it might not be inappropriately styled the Greenstick fracture of old age.

The diagnosis in this, as in the former fracture, can only be made out by a careful examination in front of the capsule in the groin. The salient angle of each in front, although detected with difficulty, will be acutely painful on pressure, and if to this we add the history, which is that of the pelvis having fallen backwards, whilst the extremity was fixed, or the extremity being rotated outwards, the pelvis being fixed, or indeed any force which would bend the neck from before backwards. That this is not an uncommon form of accident may be assumed from the fact that in the session 1879–80 I got three specimens of it. In one of these the fracture, instead of passing directly transverse through the whole thickness of the bone, passed obliquely upwards. The compact tissue in front is firmly united, whilst behind there is no union, there being an interspace between the fragments behind.

Diagnosis.—In some cases there will be no shortening; in others it may be to the extent of one-half or three-quarters of an inch, or even more. There will be slight eversion, but this will be so trifling that it could scarcely be regarded as diagnostic. But if we associate the history, the age of the patient, and the pain on pressure over the middle of the neck, with that instinctive dread of movement which usually attends fractures without displacement, a correct diagnosis may be formed.

Treatment.—The treatment is the same as in the former variety. In these, as in all other fractures of the upper end of the femur, all attempts at rotation or forcible extension of the limb should be most carefully avoided. It may be very satisfactory to the surgeon to make out the existence of a fracture by these means, but it is not at all for the advantage of the patient that a fracture which would unite by bone and form a useful limb should be converted into an ununited fracture, and leave the limb a dangling and useless appendage to the body.

THIRD SPECIES.

The Ordinary Intra-capsular Fracture.—In the two forms of intra-capsular fracture just described there is osseous union, whereas in the ordinary intra-capsular fracture osseous union is indeed of extremely rare occurrence. The question may be asked—In what circumstances do they differ? The ordinary intra-capsular fracture is caused by the weight of the body suddenly

falling upon the neck whilst the extremity is more or less abducted. It usually breaks about half an inch from the head, just at the part where it changes from the quadrilateral to the circular form, and is usually oblique from above downwards, with extensive laceration of the periosteum, and this laceration of the periosteum is the main element of the want of union.

In the former specimens the fragments are firmly held in apposition, whereas in the last, owing to the extensive laceration of the periosteum and direction of the fracture, there is a constantly recurring grating of the fragments upon each other whenever the patient makes the slightest movement, and this grating breaks the contiguous compact tissue of both fragments.

If we examine carefully a comparatively recent specimen of the ordinary intra-capsular fracture, we will find portions of the compact tissue of the outer fragment overlying its cancellated tissue, as shown in one of the specimens which I now exhibit. The disappearance of the neck is usually attributed to absorption. No doubt it is absorbed and disappears, but the main agent preparatory to absorption is movement of the fragments upon each other, which produces a constantly recurring breakage of the neck into small fragments until it ultimately disappears, and whilst this is taking place the same movement strips or tears off the periosteum from the neck. In the numerous examples of intra-capsular fracture which I have dissected there were always several bands of the untorn periosteum extending from the head to the base of the neck, and these were the only bonds of union which existed between the two fragments.

J. Walton Browne, President

Fifth Meeting Session 1880–1881 was held upon Tuesday 18th January 1881.

Present, Dr. J. W. Browne President, Professor Dill, Dr. Wales Snr., Dr. Wales Jnr., Dr. McHarry, Dr. Haslett, Dempsey, Dr. Workman, Dr. Anderson, Dr. Whitla, Dr. Smyth (Royal Hospital).

Drs. McCaw, Gilmore and Stewart were elected members of the Society.

Doctor Whitla proposed and Dr. J. W. Browne seconded the nomination of Dr. Nelson.

Dr. Dempsey read a paper upon a case of typhoid fever with unusual complications.

Paper:¹ The history of the following case of typhoid fever presents no unusual feature of interest in its early career, nor, in fact, until the subsidence of the fever. The symptoms and progress of the disease were exactly similar to the average run of cases of typhoid, except that from first to last there was a tendency to constipation rather than to diarrhoea. It was the third case which occurred in the same house, and in the same

family during the past year. The first case occurred at the end of January, and after passing through an uncomplicated attack recovered. The second occurred at the beginning of April, and also terminated in recovery. The third case—the subject of the present paper—was father of the two preceding patients.

He was thirty-three years of age, of dark complexion, tall, thin, and delicate. He suffered occasionally from indigestion and colic pains in the bowels. I saw him on the 17th November, 1880. He was then confined to bed for four days, but he was ailing for some days previous. The onset of his symptoms was of the usual character, and on the 19th. November, or the sixth day after taking his bed, some typhoid spots were noticed on his back. He had a copious eruption of rose spots during the entire fever.

His face presented the pale, earthy hue seen in typhoid; he had tenderness in the right iliac fossa; in short, the diagnosis of typhoid fever was unquestionable. The history up to the time of the first symptoms of intestinal obstruction—the complication which set in in this case—may be seen at a glance from the temperature chart which I hand round.

On December 5th, or the twenty-second day after taking his bed, he was suddenly attacked with a most violent pain on the left side of and below the level of the umbilicus, which shot down into the penis and left testicle and into the hypogastric region over the bladder. I was sent for hurriedly to see him, and found him in great agony. He was doubled up in bed, crying out with

the pain, and his body was covered with a cold, clammy sweat. He had neither vomiting nor purging. There was no pain on pressure over abdomen. Pulse, 126—weak and compressible; temperature, 102.5°. His eyes were glassy and staring. He had one motion a short time before the occurrence of pain, and one on previous day. There was some tympanites previous to this attack of pain, but not to any great extent.

He had been taking plenty of nourishment and 8 oz. of wine in twenty-four hours. I had on two or three occasions previous to this to administer castor oil, because bowels would be unmoved for three or four days. I now ordered turpentine stupes and warm linseed poultices, and a grain of opium every hour until relief of pain. After taking three pills the pain left, and he fell asleep.

6th.—Pulse, 180; temperature, 102°; perspiring freely—but this has been the case for some days; abdomen very much distended with flatus; slight pain on pressure at left of umbilicus; expresses himself as feeling very well. I prescribed an aromatic mixture and ordered turpentine stupes to be repeated. No motion since yesterday.

7th.—Pulse, 114; temperature, 99°; had a bad night; breathing is laboured; he is restless, but quite sensible. Up till yesterday he raved very much. Abdomen is more tympanitic, and the coils of intestines can be seen through the abdominal walls. To-day, besides the pain at left side of umbilicus, there is also pain over a small area to the right side of umbilicus, but it is only felt on

pressure.

He is much annoyed with flatus coming off the stomach, but he has no vomiting. His bowels have not acted since the 5th. I gave an enema of castor-oil, turpentine, soap and water, and prescribed turpentine, ether, and opium draughts, and directed hot poultices to be kept constantly over abdomen, and 1 oz. of whisky every third hour.

8th.—Pulse, 108; temperature, 100°; has vomited several times since; tympanites continues unabated; enema brought away no motion and very little flatus; very little pain on pressure to-day, and only at left of umbilicus. Gave him another enema of assafœtida, soap, and water. It was soon passed down, and only brought some flatus with it.

I saw him again this evening, with Dr. Harkin. Pulse was 108; temperature, 98.5°; vomiting was continuing. We prescribed bimeconate of morphia, solution of bismuth and hydrocyanic acid; gave another enema, and a hypodermic injection of morphia.

9th.—Pulse, 102; temperature, 99°; vomited every half-hour during the night, and the vomited matters are distinctly fœcal in colour, smell, and consistence. I gave another large enema of castor-oil and turpentine, and prescribed pulv. opii gr. i. and ext. belladonna gr. ¼ every second hour, and administered a hypodermic injection of morphia.

10th.—Pulse, 120; temperature subnormal; fœcal vomiting continues; no motion after enema. He is sinking. I gave an enema of brandy, egg, and milk.

He died the following day, December 11th, at 1 30 p.m., having vomited until a few hours previous to death, and on the twenty-eighth day after taking his bed, and on the seventh day from the attack of acute pain.

Now the only two other complications which might be confounded with obstruction in this case are peritonitis from perforation and the vomiting of exhaustion. The symptoms during the time of acute pain did not exactly correspond with those usually attending perforation; they resembled more the passing of a calculus along the left ureter, but there was no retraction of the testicle, and the pain was more severe along the penis and lower part of the abdomen than in the testicle. There was no difference in the appearance of the urine as to quantity or quality following the attack of pain from that preceding it. There was no desire to micturate. The pain did not start from the region of the kidney, but just beside and below the umbilicus.

The acute pain subsided pretty quickly, and there did not appear at any time any symptoms of general peritonitis as far as the patient's feelings were concerned. Though he was quite sensible, pressure over the abdomen only elicited pain at the point from which originated the acute pain on the first day of attack, and pain on pressure remained at this point till the last. Only on one day was pain on pressure felt on the right

side of the umbilicus.

Again, fœcal vomiting is very seldom seen in peritonitis. Murchison, in his book on Fevers, says he observed it only once. The vomiting did not occur until two days after the attack of acute pain, and it was preceded by intestinal distension and frequent eructation of flatus. In perforation vomiting usually occurs at the time of the accident. He was able to turn pretty easily on his side to have the enemata administered, but the enemata, if large in quantity, usually caused him a good deal of pain, and if the tube was introduced too high up, pain was also complained of. His pulse had not the thready feel of peritonitis, and his countenance, though anxious and careworn, had not the pinched appearance seen in peritonitis.

As to vomiting from exhaustion, I am not aware that it becomes fecal in character; but the great argument in favour of obstruction as against peritonitis and vomiting of exhaustion is the fact that no motion was passed from the bowels for seven days, notwithstanding repeated efforts by enemata for that purpose.

Taking the age of the patient, I think the probabilities are it was due to an internal hernia either in the form of a volvulus or from a constricting band, but in the absence of a post mortem examination we can only conjecture. The reason I lay so much stress on the differential diagnosis is because in any works I have consulted on typhoid fever no mention is made of intestinal obstruction as a complication.

Flint relates the case of a child dead from typhoid fever in which were found numerous invaginations, but he believed them to be post mortem. In my case it may have been an accident or a coincidence, but I think when you have intestines distended with more or less flatus, as is usually the case in typhoid fever, the movement of this flatus may very readily push a piece of intestine into a constriction, if such exist, or may cause a volvulus; and in the present case there was a history of occasional attacks of colic which may have been due to localised peritonitis, resulting in adhesions.

DR. DILL commented upon the case. He thought, for a Society like the one assembled, great benefit was found to follow an ordinary case being brought before them. Clinical curiosities were good in their way, but he learned more from a paper like the present.

He went into the diarrhœa of typhoid, and said his experience told him that decidedly constipation was more frequent and troublesome than diarrhœa in typhoid fever. He always directed his attention to the state of the bowels, and pointed out how many evils arose from neglect of enemata and mild purgation. He said he believed the case ended as a case of perforation of the bowel.

DR. WALES felt at a loss to account for the locality of the severe pain unless by supposing that a calculus descended. He did not, however, believe that this had anything to say to his death, which he believed was

owing to perforation.

DR. MCHARRY thought death occurred from simple obstruction owing to impaction, and from it he would take the lesson to always keep the bowels free and use purgation when absolutely required.

DR. J. W. BROWNE found that in all his hernia cases, when perforation occurred, vomiting ceased. He would have thought that abdominal section, as a dernier ressort, should have had a chance.

Dr. Anderson read an able paper upon the homology of the tongue muscles.

J. Walton Browne, President

Sixth Meeting February 8th Tuesday '81.

Present, Dr. J. W. Browne (President), Dr. Harkin, Esler, Dempsey, Core, Haslett, Wadsworth, McKee, John Moore, Mackenzie, J. W. T. Smith, Fagan, Professor Dill, D. Johnson, Whitla.

Dr. Joseph Nelson was unanimously elected member of the Society.

Dr. Fagan read a paper upon a rare injury of the elbow joint.

Dr. Esler read a paper upon the Medical Charities of Belfast, their uses and abuses, and after a full discussion in which most of the members expressed themselves satisfied about the existence of gross abuses, many present giving instances of such, the following committee was appointed to report upon the abuses to the Society at next meeting: Dr. J. Browne, Drs. Harkin, Fagan, Esler, John Moore, Wadsworth, McKeown, Whitla and Dr. Core.

Paper:¹ Mr. PRESIDENT AND GENTLEMEN,—The world is full of charity—a large number of the population of every country live upon charity; but amongst civilised peoples, and in Christian communities, charity has been reduced to a system, and extolled high among the virtues.

There are organisms—developments of brain and heart—that cannot but sympathise with suffering and want, and their natural sympathies find outlet in giving of their alms—some, in accordance with their nature, accompany their giving with blowing of trumpets, while others scarcely let their right hand know what their left hand doeth.

Charity is not confined to or monopolised by any one class of society. The queen, the prince, the noble, give their thousands, the mercantile and middle class their hundreds, while the labourer and artisan's gifts must be measured by the smaller coins of the realm; nor is money always the medium of expression—one may go an errand of mercy, another pass a night in silent watching.

There are marked lines of distinction in this virtue among the various sections and professions in society,

but I think I may safely say that members of the medical profession stand to-day, as they have always stood, in the first rank of benefactors to the suffering and the poor. There is no profession can claim to have done more for humanity in alleviating its suffering, supplying its wants, and mitigating its woes in their individual capacity than that of our own; yet much of the individuality has of late, and especially in the centres of population, been swallowed up by the introduction of a system of hospitals, which, useful and valuable as they are, threaten at no distant day to greatly interfere with the honest income without which even a philanthropic physician or surgeon cannot exist, unless family or fortune has provided a secure and independent living.

My object in bringing this subject before the Society is not so much to give you any information about the details of our charities as to point out the dangers which I think the system fosters, and to stimulate discussion, which may lead to some practical results.

We have been accustomed to hear from time to time at our various gatherings a wholesale and very general denunciation of the abuses arising out of the practices adopted in carrying out the charities of this town. I wish, in examining this subject, to distinguish between the uses and the abuses of our hospital system.

A great many of our so-called charities must of necessity be excluded as they are not properly charities at all. There is the poor law system, which is often classed with the medical charities. The poor law provision for attendance on the poor is in no sense a charity. It is the right of the ratepayers according to our constitution to provide for the wants, medical and otherwise, of the suffering and destitute, and however imperfect the system may be, still medical officers of health are remunerated in such a way as to leave no great room for grumbling. There is, no doubt, a large amount of work done for the amount of money received, but still it is money earned honestly and independently. The so-called charitable or benefit societies have so grown and multiplied that an enormous proportion of the artisan class are included. Many of these people are over-doctored. A man may be a carpenter and a Rechabite and have a different doctor from each society, and if he should happen to be an Orangeman as well, and perchance an Oddfellow, he may have a skilled physician for each of his principal organs; but then he pays for each, and whatever the amount may be, large or small, he has a right to get his bargain, and with him we do not quarrel. There is again the factory class, which by payment of a small weekly sum asserts its independence, keeps away from the dispensary, and on the whole gives fair remuneration to the doctor.

Now, none of these classes come much to the public hospital, and yet these constitute the major portion of our population. Where the hands in a large employ constitute themselves into a society and pay for medical services, and where a medical man undertakes to give

¹ [Dublin Journal of Medical Science, 1881, v72, p272.]

his services for a certain remuneration, I think they are on the right lines to preserve their independence, and are not guilty of medical abuse.

Hospitals are in our midst, have been, and are, increasing amongst us. It is a fair subject of inquiry—What class of patients are they treating? what class of patients ought they to treat? and what is likely to be the outcome of the present practice as far as the public and the profession are concerned?

I will try and confine myself to general statements rather than enter into details, but general statements based upon facts so well known as to make them undeniable. The public hospitals of Belfast are—the Royal Hospital, the Ophthalmic Hospital, the Ulster Eye and Ear Hospital, the Samaritan Hospital, the Skin Hospital, the Belfast Hospital for Sick Children, the Ulster Hospital for Children, the Lying-in Hospital, the old Charitable Institution, with the Dispensary for Chest Diseases, &c., &c.

First comes the Royal Hospital. It is first in importance, in extent, and, I will add, in its usefulness and its abuses. As a school of medicine—equipped with a medical staff of teachers, who devote much time and attention to the students and the patients—the Royal Hospital stands deservedly high; but for its locality and its departmental deficiency it might stand much higher. It is not by any means the fault of the medical staff that it has not kept pace with the progress of the times, and that, as special subjects have been prominently coming to the front, its narrow-minded and blindly conservative managers should have obstinately refused to equip the building with special departments as a school of medicine. Had this spirit not existed I venture to assert that few of the special hospitals now in existence would have yet been built. Is it yet too late to think of adding a wing for diseases of women and children, skin, eye, and ear? The student is thus placed at a great disadvantage in having to go elsewhere to see what should be seen and learned under the same roof of a great hospital. As a useful institution, for the treatment of certain persons and certain classes of cases, no one will find fault with the Royal Hospital—for instance, serious accidents, requiring capital operation and a long time of attendance, with skilled nursing, are admissible. Again, obscure cases, demanding the diagnosis of skilled and experienced hospital physicians and surgeons, should be admitted; a class of poor persons above the pauper has a right to the charity of the subscriber; the poor sailor and similar ill-paid benefactors of mankind should be heartily welcome. But that because the Royal Hospital is a public charity, supported by public contributions, and attended, without fee or reward, by medical men, it should admit all comers—men with incomes which would enable them to pay a moderate, nay, in some cases, a handsome fee—and that they should eat and drink and be treated gratis, is, I maintain, an utter abuse of charity. I venture to make this statement:—

That a large proportion of the cases admitted to the wards of the Royal Hospital free, are such as should be made to pay, and those who do pay, are charged rates much below what their means would warrant. In coming to look into the extern department it must be admitted that a great deal of useful work is done, and, it may be conceded, well done; but it is in this department that the most glaring abuses are met with—abuses which pauperise the community and interfere very greatly with the practice and the income of the general practitioner. It is here that reform ought to commence, and I do not think it is too much to demand for the profession that the committee of management should be called upon to confine their work within the limits of charity, and not in a wholesale, aboveboard, and even ostentatious way, for the sake of gaining public favour and applause, trample upon the sphere and directly interfere with the income of those whose very existence for some years depends upon such practice, and such fees as would arise from the work done in this extern department, for I will venture to affirm that more than half of all the patients treated are quite able to pay a small fee—such a fee as will be accepted at a private surgery. The Report just issued shows the total number treated extern—14,867. Who will say that 10,000 of these could not pay a shilling for advice and medicine, or for surgical dressing? and taking each as being attended to twice, a thousand pounds is thus kept out of the pockets of the general practitioner.

The next Belfast charities we have to notice are the special hospitals known as the Benn Charities, with which may be classed the Ophthalmic Hospital. There can be little doubt but that these charities, situated as they are and under separate management, are the outcome of the dog-in-the-manger policy of the former managers of the General Hospital. Science was progressing; special departments were recognised and being introduced in nearly all the leading hospitals in England and the Continent; young medical men of talent, and with special training, wanted a field for observation and work, but over the portals of the medical school of this town was written large “No admission here.”

But mind, spirit, soul, cannot be fettered even by obstruction chains forged in do-nothing workshops. Hence one man, and another, and another find a platform from which to speak and teach, and the language to-day is unmistakable—“Nothing succeeds like success.” I will not differentiate among these hospitals. They are all worked on the same general principle; they are nearly self-supporting; and while all are not perhaps equally careful to prevent abuse, yet the safeguards are of such a kind that, in the hands of men of high principle and good practical common sense, I am satisfied they will not do anything to abuse the spirit of true charity, nor infringe on the domain of the general practitioner.

Regarding the practice of receiving pay patients, there is, I imagine, as much room for abuse as in the admission of free patients. A class above those who are entitled to receive hospital attendance are induced to come, or excuse their rank and position by coming and paying a fee, however small, for admission or medicine. To prevent this abuse it lies with those at the portal of admission to institute rigid inquiry. I am decidedly of opinion that the public receive more benefit and the profession suffers less injury from the purely special hospitals than from the more general. It is an advantage to the general practitioner to have the opinion of a specialist, when it is known that his terms are such that the patient is not likely to be induced to leave his ordinary attendant.

And now, coming to the two Hospitals for Children, I will not enter upon the questions—Why there are two? Whether there be room for two? Which was first in the field? Which excels in usefulness or abuses?—but deal with both as they affect the public and the profession. In these hospitals there are some 12,000 children seen every year, with twice that number of attendances. That they do a large amount of useful and important work is certain; that a large proportion of that work is a relief to the dispensaries there can be no doubt; and that very many of the miserable mothers who bring their children cannot afford to pay anything I am thoroughly convinced. One of these hospitals has an evening hour three times a week, which is especially useful to mill-workers and others engaged in labour through the day. I think the abuses are less at this particular time than on other occasions, but I am not prepared to say that there are not, on every occasion the doors are opened, some, and on some occasions many, who could, and who should be made to pay at least for medicine; and I do think the time is not far distant when the profession should take a stand and put some check: on the wholesale way in which patients are drawn into the net of so-called charity. For abuse and infringement on the domains of the open surgery I class the Children's Hospitals with the extern of the Royal. In my opinion about half of the patients of both should be sent about their business, and thus the profession would benefit to the amount of £2,000 a year, and the independence of the community would be preserved.

Of the Lying-in-Hospital I may only say that its usefulness I will not question—of its abuses I have never heard. Provident Dispensaries have not succeeded in our midst, and I am doubtful if they ever shall. Where they are established, I am told, they are generally looked upon as the flag of distress of some needy and often half-qualified medical man. The Belfast Charitable Society is, I believe, the oldest hospital in Belfast. It was incorporated in 1774, but, as it is not a public hospital, does not come within our criticism.

I cannot close this paper without glancing at the question of how much individual members of the profession

are benefited from their connexion with an hospital; and, first, that the appointment to the Royal Hospital has been the making of the reputation of some of the staff I think not unlikely. We cannot suppose, and I dare not venture to assert in this Society, that superior talent or attainments are to be found in all the members of an hospital staff, or perhaps in any of them, to that met with in others who have no appointments, but by this means they have a large field for observation, and are brought into contact with the students who in time call in their old teachers as consultants, and in this way members of an hospital staff profit.

There is a great temptation to extern workers to get all the patients they can, and thus extend their observation and connexion. I do not blame them, but as a disinterested member of this Society I must express my opinion that the usefulness to the few must not be allowed to create abuses which extend to and interfere with the many.

As far as I can see the chances for a young man making a practice with the present state of things is one of slow, trying, laborious work. What, between necessity on the one hand, and an over-doctored, pauperised population who are being taught not to pay, on the other, the description of a young beginner is very much like that of the Patriarch regarding Issachar: "A strong ass crouching down between two burdens."

The great advantage of an appointment in a special hospital is to fit a man for that special work, and to extend his reputation in that branch if successful.

In a Children's Hospital one is made familiar with the various phases of children's diseases, and only in this respect is it remunerative. Experience brings confidence, and a consciousness of knowing one's work is both pleasurable and profitable.

The conclusions I would adduce are: That a large public hospital is necessary for the purpose of teaching, and the treatment of urgent and deserving cases, and that it should be fully equipped with special wards, appliances, and every necessary accommodation so as to facilitate the work, and save the time of both teacher and student. That the cases treated in hospital should be from such classes of the community as will at once benefit the suffering, economise the funds placed at the disposal of the managers, and not interfere unduly with the patients of private practitioners. That there are abuses in the working of the out-patient department of all the hospitals, and that the time has now come when this Society should direct the attention of the managers of the various charities to this matter, and request them to put such checks on admission as will prevent a continuance of these abuses.

R. F. Dill, Ex-President

Seventh Meeting February 22nd Tuesday.

Present, Professor Dill Ex-President in the chair, Drs.

Gordon, Wales Snr., Workman, Dempsey, Wadsworth, McCaw, Graham, Haslett, Clements, Kevin, Whitla, Fagan, Speer.

The report from the committee appointed to report upon the abuses of the medical charities was submitted and after a long discussion involving the consideration of many amendments, the following report was agreed to:

REPORT ON THE ABUSES OF THE MEDICAL
CHARITIES OF BELFAST.

A Committee was appointed by the Society on February 8th, 1881, to consider and report upon the abuses of the Medical Charities. Their report as amended and revised by the Society, at a meeting specially summoned for the purpose, upon February 22nd, 1881, is as follows:—

1st.—That provision is made by the Poor Law system for the medical treatment of the poor.

1st.—At the Dispensaries.

2nd.—By visiting at their own homes.

3rd.—By hospital accommodation at the Union Infirmary.

2nd.—That it is necessary in a large town like Belfast to have a General Hospital, with departments for the treatment of Special Diseases, and for the reception of urgent cases, and also for the purposes of clinical instruction.

3rd.—That many persons for whom the Medical Charities of Belfast are not intended, largely avail themselves of the advantages of the various Institutions, owing, chiefly—as we think—to the lax system of admission, and they thus impose upon the Charitable Public and the Medical Profession.

4th.—That injurious results arise to the persons themselves who take advantage of these Charities, as they are thus educated to foster deception and destroy their spirit of independence, whilst amply able to pay for Medical aid.

5th.—That, in consequence of these abuses, the Medical Profession feel aggrieved, as not only is Hospital work greatly augmented, but the interest of the general Practitioner is unjustly interfered with.

6th.—That, although abuses exist both in the Intern and Extern Departments, they predominate to a much greater degree in the treatment of out-patients; and we are of opinion that this department in the several Hospitals should be greatly restricted, and that careful examination into the means of applicants should be instituted.

7th.—That we recommend that a competent person be appointed to exercise close supervision over all those applying for relief at the Extern Departments of the various Hospitals.

8th.—That we disapprove of any member of an Hospital staff receiving fees for services rendered to

any patient whilst under Hospital treatment.

9th.—That a copy of this Report be sent to the Managing Boards of the different Hospital Charities in Belfast.

W. WHITLA, M.D.,
Hon. Secretary.

February 22nd, 1881.

The 8th and 9th resolutions not being embodied in the original report of the committee were proposed and seconded by Drs. Workman and Wales Snr. and passed unanimously.

A deputation consisting of Drs. Dill, Wales, Esler and Whitla was appointed to bring the matter before the board of the Belfast Royal Hospital.

J. Walton Browne M.A. M.D., President

The Eighth Meeting of the Society was held upon Tuesday March 8th 1881.

Present, Dr. J. W. Browne in the chair, Professor Gordon, O'Neill, Kevin, Esler, McCaw, Clements, Anderson, Smith jnr., Mackenzie, Whitla, Haslett, McHarry, James Moore, and many students.

Professor Gordon read a paper upon extra-capsular fracture and showed a large number of beautiful specimens.¹

Paper:² *An extra-capsular fracture is defined as a fracture of the neck of the femur external to the capsule. It would, however, convey a more accurate idea of the nature of the accident to define it as a fracture through the base of the neck. Usually in front the fracture runs along the anterior inter-trochanteric line, above where the neck joins the apex of the trochanter, thence internal to the digital fossa, and downwards along the internal margin of the posterior inter-trochanteric line, till it passes through or above the lesser trochanter. The fracture is thus seen to follow a course which corresponds to the circumference of the base of the neck, which is quadrilateral in form, as described by anatomists, and widens slightly in its antero-posterior diameter as we proceed from above downwards. When a person advanced in life falls upon the outer part of the great trochanter, the limb comes to be at rest; the weight of the body through the pelvis being in projectile force strikes the head, and drives the base of the neck into the trochanter. The direction of the force is nearly parallel to the long axis of the neck, and in the direction in which the neck is mechanically strongest and its base weakest. I have no hesitation in stating that this is the mode in which the extra-capsular fracture is produced.*

If we examine carefully a good collection of these fractures it will be found that no two of them are exactly alike, differing slightly from each other, but generally presenting a remarkable resemblance. In all

¹ [Part one of a two-part lecture. Part two was given on 17 May 1881 (see page 1432).]

² [Dublin Journal of Medical Science, 1881, v71, p499.]

of them the fracture may be said to consist of three fragments—one formed by the head and neck, a second by the apex of the trochanter, the posterior inter-trochanteric ridge, and more or less of the outer and posterior part of the trochanter, and the third by the upper end of the shaft, with a portion of the trochanter attached.

If the reader has before him a femur, and if he draws horizontally a figure, leaving the curve of the outer surface of the trochanter extending, from the anterior to the posterior inter-trochanteric line, this figure will approach closely to a semicircle. Draw across this semicircle a diameter, which may be regarded as the base of the neck. It will be at once seen that the diameter or base of the neck can scarcely penetrate the semicircle without tending to flatten it more or less, a force be applied to the diameter or base of the neck which drives it into the semicircle or trochanter, the effect of such a force will be at once apparent. In the act of breaking, the base of the neck or diameter widens the semicircle, and the broad base of the neck widens the diameter of the trochanter, which then rapidly diminishes. The effect will be a fracture of the trochanter varying in different cases according to circumstances, such as the direction, amount of force, and the fragility of the bone.

Women are much more subject to extra-capsular fractures than men, for several reasons—1. Females generally lead a more sedentary life, and therefore their bones are more atrophied, and are, in consequence, more easily broken. 2. The angle approaches more nearly to a right angle than in males, and therefore a force acting on the trochanter has more power in driving the base of the neck into the trochanter. 3. As we advance in age, the posterior inter-trochanteric ridge becomes widened, and the angle of reflection of the compact tissue becomes more a right angle, and penetration is thereby facilitated. Old age is the main predisposing cause of both extra- and intra-capsular fractures, and the comparative frequency is owing to the manner of falling.

Falls upon the trochanter are the most common causes of this accident. The extra-capsular fracture will be found to be more frequent in extreme old age than the intra-capsular. If the direction of the force be parallel, or nearly so, to the axis of the neck, the fracture will be found to be extra-capsular.

On the other hand, if the force has been at right angles to the axis of the neck, as in forcible abduction of the limb, the fracture will be the ordinary intra-capsular, and from the nature of the force attendant there will be great laceration of the periosteum; and for want of the periosteum there will be upward and downward movements as well as those of rotation, and on this account there will be no osseous union. If a force be applied from before backwards, or at right angles to the neck, there will be a trifling laceration of the perios-

teum and osseous union, if matters have not been aggravated by attempts to elicit crepitus by rotation and extension to enable us to diagnose a fracture. The weakest point of the neck of the femur, to a force applied at right angles to its axis, is at the point where it changes from the quadrilateral to the circular form; this is about one-third of an inch from the head, and is the weakest point of the neck when force is applied with the limb abducted.

In leaping, the extremities are approximated, and the weight of the body at the ilio-femoral articulation is received upon the upper and outer part of the head of the femur, through which it is obliquely transmitted thence to the inner surface of the neck. The chief force of the shock is received by the lower part of the base, between the lesser trochanter and the ridge which forms the boundary between the anterior and internal surfaces of this part. But the upper end of the femur is bent forwards, the effect which is to strengthen this part of the bone in a remarkable manner against shocks, which are thereby diffused over the strong base of the neck internally, and also over the anterior and internal ridge and the compact tissue forming the anterior surface of the upper end of the shaft. The effect of the momentum from leaping or lifting heavy weights is to force the head into the acetabulum and diffuse the shock against that part of the neck and upper end of the shaft to which nature has given it special strength to resist.

If we now direct our attention to the upper and posterior part of the neck it will be at once apparent that this part of the neck suffers very little pressure. I think, when the limbs are approximated, and when force is applied vertically to the upper end of the femur, it is not likely to suffer either dislocation or fracture. I have not met with a single instance of extra-capsular fracture caused in any way but by a fall on the great trochanter. Abduct the femur even to a slight degree, the point of impact becomes more external, and the weight of the body falls upon it almost at a right angle to its axis, and breaks easily—the production of the ordinary intra-capsular fracture being the result. The specimens which I have of extra-capsular fracture resolve themselves into five Forms, each of which presents some character slightly differing from the others, thus affording us an explanation of the various signs which might puzzle us in forming a correct diagnosis if we took only a general view of the accident.

First Form.—In the first form the force is received upon the upper and posterior part of the base of the neck, which gives way, and at the same moment the fracture in front takes place. Above and behind, the line of fracture varies very little, but in front it may pass through the anterior inter-trochanteric line, external to it or even nearly to the outer border of the anterior surface. Below, it passes into or above the lesser trochanter.

The trochanteric fragment is small in comparison to that of the second form. The eversion of the limb is usually well marked, but sometimes to such an extent that the toe looks directly outwards. If we examine a specimen of this form the rotation outwards of the shaft of the femur upon the neck appears so plain as not to admit of doubt. This theory has always appeared unsatisfactory to me. I have taught for many years that the eversion was due to the rotation of the shaft of the femur upon the base of the neck. I always thought that there was more than I had observed. I therefore determined to pursue my inquiries by commencing with the cause of the accident. All my inquiries taught me that it was produced by a fall upon the outer surface of the femur. The extremity is usually extended, and lying with its outer surface upon the ground. The extremity will be fixed, and cannot turn outwards, as the outer margin of the foot lies in contact with the ground. Therefore, so far as inquiry into the history of the accident was concerned, the theory of rotation outwards of the shaft upon the base of the neck was no longer tenable. It is a physical impossibility. I next commenced an examination of the specimens. I took the sound femur, and placed it on its anterior surface, with the aspect of the *linea aspera* looking directly towards the ceiling; then, taking one of the specimens in which there was the greatest amount of rotation outwards, I was surprised to see that the aspects of the head and *linea aspera* were the same, and that, in the specimens the head had undergone a rotation backwards to a little more than a right angle, probably to the extent of 92° or 93° . Other specimens showed similar rotation, varying in amount from 30° and upwards. This examination revealed the true explanation of the eversion in this accident. It is not a rotation of the shaft of the femur upon the neck, but of the base of the neck upon the shaft, whilst it lies with its outer side on the ground, fixed by the weight of the body and in contact with the ground. The theory of eversion of the extremity by rotation of the shaft upon the base of the neck is therefore untenable, as the position of the limb renders such rotation impossible. When the patient falls upon the outer surface of the thigh the extremity comes to be at rest, and the head of the femur looking upwards receives the weight of the pelvis on the inner side of the head, which from its position looks directly upwards; the weight thus received upon the head is transmitted through the neck to its base—that being the weakest part to a force thus applied—gives way, and breaking penetrates the trochanters. The neck being broken, the pelvis losing its support falls backwards, carrying with it the head, causing rotation from before backwards of the base of the neck upon the shaft. This rotation will continue until the posterior surface of the pelvis comes in contact with the ground.

In order to form a true estimate of the views set forth regarding the mode by which the fracture is produced,

and to explain its various forms and their signs, let the femur be placed on its outer surface, the head will look upwards, and it will also be extended, and whatever movement takes place at the ilio-femoral articulation will be that of the pelvis upon the head. The momentum of the pelvis will be received upon the head, and transmitted from it to the neck, and thence to the base of the neck. It must always be borne in mind that the head fits accurately into the acetabulum, and also that the momentum of the pelvis will be transmitted in a line perpendicular to the point of impact. As the head receives a general support from the acetabulum, it is not broken, though it may be in a state of extreme atrophy.

When the pelvis is placed upon the head, with its inlet looking upwards and forwards, the point of impact will fall behind the axis of the neck, and the fracture will be the First Form. If the inlet looks directly forwards, the impact will be in front of the axis of the neck, and the Second Form will be the result. If the ground upon which the patient falls inclines downwards, the upper part of the neck will receive the greatest shock, and deep penetration of the neck above will take place, with an increase in the angle of the neck. This unnatural increase of the angle of the neck is the main ground upon which the Third Form is based. If the impact be upon the lower part of the head, the lower part of the base of the neck will receive the greatest degree of shock, and the base, being dense at this part, splits the shaft, and produces the Fourth Form.

A very slight movement of the pelvis upon the head of the femur, in the various directions above mentioned, suffices to throw the shock upon the back, fore, upper, or under part of the neck respectively, producing fractures having results widely different from each other. I may here remark, that although the various forms of fracture of the base of the neck may be primarily the same, yet the secondary or subsequent lesions and displacements will be very different, according to the direction and amount of force and the fragility of the bone.

In this, the first form, when the patient is placed supine, we see that the injured thigh is in a plane anterior to that of the other side to a greater degree than in any of the other forms, while the limb is shortened and the toes very much everted, and the upper end of the shaft nearer to the anterior superior spine of the ilium, resembling in a remote degree the approximation that occurs in dislocation, upwards and backwards on the *dorsum ilii*, but with the toes remarkably everted. That this accident could be mistaken for a dislocation on the *dorsum ilii* is difficult to understand, as in fracture the outer surface of the femur and external condyle look backwards and outwards, whereas in a dislocation it looks forwards and inwards; and to produce the amount of rotation outwards in the healthy femur would require the head of the bone to have left

the acetabulum and be placed on the pubes. In most instances of this form of fracture the neck forms a right angle with the shaft, but in some the angle is not much altered, but the anterior aspect of the neck, instead of looking directly forwards, looks forwards and upwards, the neck being rotated on its axis as much as 15° or 20°.

The fracture through the base in front is external to the anterior inter-trochanteric line, where it might be easily felt very prominent behind and external to the tendon of the rectus femoris muscle. This prominence with the fulness in the groin is so easily felt, and contrasts so remarkably with that of the opposite side, that the diagnosis might be based upon it alone. As the base of the neck has penetrated behind obliquely outwards and forwards, the trochanteric fragment is usually not large, nor is it displaced much out, but a little backwards and mostly inwards, lying within a short distance of the head and acetabulum; but this inward displacement of the trochanteric fragment is more apparent than real, for were we to deduct the amount of penetration by the neck it will be found very little displaced—therefore prominence of the base of the neck in front, widening and displacement of the trochanteric fragment, would be diagnostic.

Diagnosis.—So the diagnostic signs of this, the most frequent of all the forms of extra-capsular fracture, are as follows:—

1. The history of a fall on the great trochanter.
2. Well-marked shortening.
3. Eversion of the foot.
4. Prominence of the base of the neck easily detected by manual examination, external to, or behind the tendon of the rectus femoris muscle.
5. Increase of the antero-posterior diameter of the upper end of the femur.
6. Pain on pressure at the upper part and front of the shaft.
7. The shaft is approximated to the anterior superior spine of the ilium.
8. The injured femur is on a plane anterior to that of the opposite side.

Although this form scarcely presents a single sign in common with dislocation of the head of the femur on the dorsum ilii, yet, as the latter is the only luxation with which it is possible to confound it, subjoined I give the differential diagnosis:—

Extra-Capsular Fracture.

1. Cause.—A direct fall upon the trochanter.
2. Most common in advanced life.
3. Foot much everted, sometimes pointing directly outwards.
4. Limb shortened.

Dislocation on the Dorsum Ilii

1. Cause.—Forced rotation inwards of the femur.
2. Extremely rare, almost unknown in advanced life.
3. Foot inverted.
4. Limb shortened.

Extra-Capsular Fracture.

Dislocation on the Dorsum Ilii

5. The head may be easily shown to be within the acetabulum by gently flexing and extending the femur by the hand, placed behind the lower end of the femur.
 6. The outer surface of the trochanter looks backwards.
 7. The base of the neck may be felt prominent in front, and there is great increase in the antero-posterior diameter of the trochanter.
 8. Acute pain on pressure along the line of fracture, in front, above and behind.
 9. The displacement of the trochanteric fragment may be easily felt by passing the fingers along the posterior branch of the *linea aspera*.
 10. A groove may often be felt when the trochanteric fragment is separated.
 11. The inter-trochanteric line behind cannot be felt.
 12. In cases of great eversion of the foot in aged persons, from a fall upon the great trochanter, this form may be diagnosed, as in none of the other varieties does the same amount of eversion take place.
5. The head rests on the dorsum ilii behind and above the acetabulum, and the movements are restrained and difficult.
 6. The trochanter is approximated to the anterior superior spine, its outer surface looking forwards.
 8. No pain, or very slight pain, when pressure is made over the posterior part of the trochanter.

Treatment.—I have often asked myself, as well as others, upon what principle can a long splint be serviceable in this form of fracture? The head and neck are firmly fixed in the acetabulum, by the capsular ligament. The base of the neck is deeply driven into the cancellated tissue behind, whilst it is prominent in front. The trochanteric fragment, to which are attached the *glutens minimus*, *pyriformis*, the internal and external obturators, is approximated to the acetabulum behind, and is fixed in this position by these muscles, and the only medium of connexion between it and the shaft is the tendon of the *gluteus medius* and fibrous tissue on the outer surface of the trochanter. The foot being greatly everted, in order to apply the splint we must rotate it so as to make it look forwards. Now in this movement the base of the neck forms the fixed point upon which the shaft must move in this rotation, thereby separating the base of the neck entirely from the trochanter, except in front. The limb being shortened, when extension is made it separates the shaft from the head and neck, which is fixed by the capsule, as already stated. The trochanteric fragment being also fixed by the muscles previously mentioned, would also be separated by extension; indeed the effects of extension would be to draw the three fragments from each other, and render a limb which would otherwise be useful into one that was comparatively useless. I could hardly conceive a more useless or irrational practice,

and one without a particle of sound anatomical knowledge in its favour, not to speak of confining the patient in a recumbent posture, thereby entailing certainly very serious consequences, and often fatal results.

The treatment which I have adopted is that of putting the patient into a comfortable and easy position, and allowing him to move as he may wish. I know of no instance in which the fragments were detached or separated from each other by any rash or imprudent movement on the part of the patient. The accident is usually extremely painful, and any movement made by the patient aggravates that pain, and therefore when they change their position, to relieve the organic suffering from pressure, they do so with the greatest gentleness and caution. Some will experience the greatest relief by lying midway between the side and back positions, the outer and posterior surface of the femur resting on and supported by the bed; others cannot suffer the limb to be extended, but will have it bent at right angles to the pelvis, as affording to them the greatest freedom from pain; others will adopt an intermediate position. The rule which I adopt is to let them select their own position, and support the limb as they find it most comfortable.

Dr. Anderson read a paper upon the homology of the omohyoid.

Paper:¹ THE omohyoid muscle occupies a somewhat isolated position, and, as usually seen in man and many vertebrates, attached by one extremity to the bone of the upper extremity and by the other end to the hyoid bone mediately or immediately, it has given rise to much discussion.

Professor Henle, in his handbook, states that the anterior belly of the omohyoid is a muscle analogous to the sternohyoid, the posterior to a digitation of the serratus magnus, and the tendon uniting the anterior and posterior belly has the significance of a cervical rib. As the lowest cervical rib is not developed the two muscle bellies pass into one another by means of a tendinous inscription.²

Professor Gegenbaur from an examination of the different varieties of the muscle was led to a different result. The varieties which seem to point to the conclusion at which Henle arrived are described by Theile, Gruber, Luschka, and other anatomists. The muscle described by the first anatomist as attached to the upper border of the scapula at the place of origin of the normal omohyoid (which was absent in this case) and by its opposite extremity to the first rib has been regarded by succeeding observers as a variety of the subclavius. The instance given by Professor Gruber³ is named subclavius by him, and the cases mentioned by Luschka, Gegenbaur explains in a similar manner, and shows

that these cannot be regarded as transitional forms of the omohyoid.¹

The same anatomist points out that tendinous inscriptions have not usually the significance of ribs, and adduces the examples of the biventer cervicis, complexus and rectus abdominis, where the tendinous intersections indicate simply the remains of the original separation of the muscle into a number of segments corresponding to the body metamers. The presence of a tendinous intersection at the lower extremity of the sternohyoid serves to strengthen the relation, as it shows the intimate connexion of the sternohyoid and omohyoid.

The tendinous intersection of the omohyoid being generally well marked, and sometimes of considerable length, is explained by the facts that the muscle here makes a bend and it is in relation with the deep cervical vessels. The varieties met with in the animal series and in man show that the omohyoid belongs to a muscle group which is represented in man by the sternohyoid and sternothyroid.

This group is supplied by the cervical nerves coursing in the hypoglossal path. Secondly, in the lower forms the origin of this muscle group extends from the sternum to the clavicle and is continued to the scapula. In crocodiles an episterno-hyoideus is present, which in the saurians becomes an episternocleidohyoideus, and in platyductylus (Sanders) extends to the claviculo-scapular articulation, whilst it passes quite to the scapula in uromastix (Furbinger). By separation of individual portions of this muscle, muscles arise distinguished as the sternohyoid, sternothyroid, cleidohyoid, and omohyoid—a simple absence of muscle substance giving rise to the varieties observed in man and animals. The most frequent variety is the cleidohyoid, which in man, though frequently present, is not usually developed. This variety occurs once in every 15 subjects according to Hallett.² In 373 subjects, 8 on both sides, 4 right side only, 5 left side only, majority in middle third, rarely inner third (Turner³). One in 12 subjects (Gegenbaur⁴).

Finally, the fascia uniting the omohyoid to the clavicle is explained by the retrograde metamorphosis of the cleidohyoid. This is shown by the fact that muscular fibres are to be found in the fascia having the same character and course as those of the cleidohyoid; and the fascia is attached to the muscle, and more firmly to the tendon, with which it is intimately connected. This fascia, which extends from the lower inner border of the omohyoid to the clavicle, is not to be regarded as a portion of the deep cervical fascia.

Albrecht⁵ shows that although the omohyoid is part or

⁵ Beitrag zur Morphologie des M. Omohyoideus.

is represented by part of a continuous muscle layer in certain vertebrates, yet in a very considerable number of animals the omohyoid is present as a distinct muscle or is absent altogether, and that it is recognisable in the lower classes.

In mammalia we find it in the lowest forms; in the ornithodelphia it is almost the same as in man. In echidna,¹ according to Mivart, the omohyoid does not much deviate from the condition found in the higher mammals (man). In ornithorhynchus² the omohyoid is present and inserted with the mylohyoid into the hyoid bone; a sternohyoid is present as a distinct muscle. In the marsupials³ the omohyoid presents a scapular origin. The omohyoid is wanting in the edentates (Owen, Humphry,⁴ Macalister,⁵ Galton⁶). The ungulates have an omohyoid. In the ruminant artiodactyla the origin is somewhat variable from the transverse process of the last cervical, in the giraffe from the transverse process of the third cervical. The pachydermatous artiodactyla (Humphry⁷) possess an omohyoid which passes over the anterior edge of the scapula to the upper border to be connected with the radial tubercle of the humerus and the deltoid by fibrous tissue. In the hippopotamus,

according to Professor Humphry, the omohyoid passes from the side of the basihyal and the subhyoidean septum to the under surface of the occipito-humeral part of the trapezius, which it joins at an angle and is united to it by an inscription.¹ In the horse,² of the perissodactyla, the omohyoid arises from the coracoid process. The omohyoid is absent in the carnivora, but some possess it, as meles, hyæna, lutra. Of the pinnipedia, Prof. Humphry⁵ states that this muscle in phoca⁵ is continuous with the sternohyoid, forming a broad muscle which is inserted into the sternum, the ulnar tubercle of the humerus, and a fascial band between the two, similar—as Albrecht remarks—to the arches of the diaphragm or the tendinous arch in connexion with the adductor magnus. In the descoïd placental mammals an omohyoid similar to man has been described in tarsius and cheiromys. Rodents that have a clavicle have an omohyoid. Of the insectivora no erinaceous muscle is present. According to Professor Macalister, in the vespertilionidæ the omohyoid is slender and distinctly biventral. In the phyllostomine bats scarcely a trace of tendinous intersection. In noctulina a band arises from the middle of the clavicle and joins the sternohyoid midway between the origin and insertion; above the point of union is a tendinous intersection.³ In primates

the omohyoid is similar to that muscle in man. In troglodytes aubryi an omocleidohyoid is present (Grateolet).

Albrecht¹ tabulates the varieties of the omohyoid, thus:—

1. Mammals in which a muscle homologous to the omohyoid is absent—
 - (1) Edentates, (2) many Carnivora, (3) Pinnipedia, with the exception of phoca, (4) Rodentia without a clavicle, (5) many of the Insectivora, (6) Cheiroptera, with exception of noctulina (see Macalister).
2. With the omohyoid resembling closely the omohyoid of man—
 - (1) Ormithodelphia, (2) Didelphia, (3) Meles, hyæna, lutra (Carnivora), (3) Prosimiæ, (4) Rodentia with clavicles (5) Insectivora erinaceus, (6) Primates, with the exception of troglodytes aubryi.
3. With a musculus coracohyoideus, Equus.
4. M. cleidohyoideus, Noctulina.
5. M. omocleidohyoideus, A. Troglodytes aubryi.
6. M. omobrachio-hyoideus, Sus.
7. M. trapezio-brachio-hyoideus, Hippopotamus.
8. M. sterno-brachio-hyoideus, Phoca.
9. M. spondylo-hyoideus, Ruminantia.

Of these varieties the first five are known to occur in man, and have been recorded by anatomists; of Nos. 6 and 8 examples must be extremely rare. An example differing slightly from these forms I shall give later on. Instances have, however, been given which approach the conditions given above; thus, Hallett and Schwegel show detached bundles of the posterior belly inserted into the sixth cervical transverse process or into the sterno-mastoid and into the fascia of the scalenus (Hallett). Kelch and Grüber have mentioned a muscle which passes between the outer end of the clavicle and the transverse processes of one or several cervical vertebræ. A cervico-costo-humeralis is described by Prof. Gruber, which was inserted into the smaller tuberosity of the humerus by two tendons into the transverse process of the sixth cervical vertebræ and the anterior end of the first rib cartilage. The other varieties referred to by Prof. Gegenbaur, Albrecht gives, and remarks that the examination has been confined to the mammalian and reptilian type. These varieties are the M. episternohyoideus of crocodiles, the episternocleidohyoideus of saurians, and the episternocleido-omohyoideus superficialis of the mastix. The evidence in favour of the omohyoid belonging to the system of the rectus abdominis, amongst the mammalia, Albrecht points out, is based principally on the presence of a cleidohyoid in a noctulina, an omocleidohyoid in a troglodytes aubryi, and the musculus brachio-ster-nohyoides of phoca. In opposition to this the monotremes present a condition of this muscle resem-

bling closely that of the higher forms. On the other hand, the amphibia, and not the reptilia, are to be looked upon as morphological allies of the mammalia. In the frog an omohyoid is known to exist, and the same muscle has been described in many other amphibia. Humphry has described the muscle in menobranch and cryptobranch. The condition in uromastix may be looked upon as a union of the omohyoid with episternocleidohyoid.

Albrecht shows that in fishes—of which he takes as examples spinax acanthias, raia clavata, acipenser sturio, and gadus morrhua—interbranchial muscles belonging to the internal oblique layer of Humphry are present. Thus, in spinax six interbranchial muscles—the last or (sixth) being the muscle extending from the shoulder girdle to the last branchial arch (omozonio-branchialis), the latter not necessarily the morphological equivalent of one of the others—are present, united with the mesial layer or layer of the rectus (omozonio-hyoides); external interbranchial muscles, belonging to the external oblique layer, are present; in raia the external and internal muscles are present; in acipenser the former are wanting, and the sixth of the latter (omozonio-hyoides) gives evidence of separation into two muscles; in gadus all the external and the first two internal branchial muscles are absent, the sixth being divided into two separate muscles; in amphibia the first four interbranchial muscles present variations—they are absent in tailless batrachians; the fifth and sixth have the following arrangements:—the latter being divided into two, one or other or both being persistent. The sixth dorsal interbranchial is present in siren, proteus, and menopoma—absent in menobranchus, cryptobranchus anoura, and others. The sixth ventral internal interbranchia, with the fifth, is united in one muscle, the omohyoid—the posterior part of which is represented by the sixth, the anterior by the fifth, interbranchial muscle—in proteus, menopoma, and amphiuma, where both muscles join the sternohyoid; in cryptobranchus, where the anterior belly joins the sternohyoid; and in the tailless batrachians, where both bellies are free.

The observations of Albrecht, as will be seen, serve to confirm those made by Humphry, as far as the continuation of the internal oblique layer forwards to the neck is concerned, and as the subject requires a reference to the views of the latter anatomist, I shall here summarise them.¹

The internal oblique stratum represented by that muscle in the abdominal wall is continued to the thorax as the external intercostals, and here the ribs are developed in this stratum as well as the sternum and the limb girdles, and is continued into the neck, where the hyoid bone is developed also in this layer. In the abdomen, the internal oblique, the quadratus lum-

¹ Albrecht Loc. cit P. 11.

¹ Observations in Myology. P. 123.

borum, rectus, and pyramidalis; in the thorax, the external intercostals, levatores costarum, rectus thoracis, rectus thoracis lateralis sternocostalis; in the neck, the scaleni, rectus capitis lateralis, sternohyoid, sternothyroid, hyoglossus, geniohyoglossus, and the middle and inferior constrictors of the pharynx. To the same stratum may be referred the styloglossus, the stylohyoid, the stylopharyngeus, the digastric and the superior constrictors.

The muscles that pass to the shoulder girdle are those which pass above the glenoid cavity belonging to the serratus or costos-capular group, which group is prolonged into the omohyoid and levator anguli scapulæ anteriorly, and those that pass to the girdle below the glenoid cavity, the costo-coracoid group, including the sterno- or costo-scapularis and the subclavius. The nerves to the limb serve to separate the groups in question.

In cryptobranch (p. 11) the internal oblique fibres acquire an anteroposterior direction near the mesial line, and are continued into the deep fibres of the rectus. Anteriorly the omohyoid has a very similar relation to the sternohyoid.

If, then, we trace the middle layer forwards, we have as its representatives, attaching the limb to the trunk, the serratus and levator anguli scapulæ posteriorly, the costo-scapular or costo-coracoid (subclavius) attaching the limb to the trunk anteriorly, the nerves to the upper limb separating the anterior (lower) from the posterior (upper) group. The nerves which separate the subclavius from the serratus separate the omohyoid from the same muscle.

The omohyoid and subclavius present many important points of resemblance, and these will be more readily seen if the varieties of the latter muscle be compared with those of the former.

In emys europæa the subclavius arises from the under part of the first costal plate, and is inserted into the suprascapula and the contiguous part of the scapula.¹ In the crocodile the epicoraco-humeral muscle, which Professor Rolleston regards as the homologue of the subclavius, arises by two heads—the inner from the visceral surface of the scapula, the outer from the precoracoid and from the prescapular portion of the preglenoid expanse. The inner is intimately connected at its insertion with the pectoralis major, and, together with the tendon of the outer head, occupies a position between the deltoid and pectoralis major. The insertion of the omohyoid corresponds with the origin of the preglenoid head, and the fibres of the two muscles are, to some extent, continuous with one another, at least in young specimens.² In the emu, according to the same anatomist, the epicoraco-humeral muscle arises from the mesial part of the sternum or “rostrum” of the bone, from the coraco-clavicular membrane, and from an

irregularly quadrangular preglenoid headland constituted by the scapula and coracoid; it is inserted into the humerus above and internal to the deltoid, and superficial to the coraco-brachialis.

In apteryx, according to Professor Owen, a portion of the pectoralis minor, which he called subclavius, arises from the anterior angle of the sternum, and is inserted into the coracoid.¹

In echidna, according to Mivart,² no pectoralis minor is present; a small muscle arises from the first rib, and is inserted into the coracoid. The subclavius of Owen is inserted into the coracoid in ornithorhynchus. This rectus is inserted into the coracoid at no great distance from the epicoraco-humeral (the homologue of the subclavius of other mammals).

In the wombat of the marsupialia the subclavius arises from the first rib, and is inserted into the outer end of the clavicle, and by means of the fascia covering the supraspinatus into the whole length of the spine of the scapula. It is joined by a fine tendon or thin muscle that arises from the sixth costal cartilage. A fascicle of the rectus abdominis passes into this muscle near its attachment to the rib.³

In dasypus sexcinctus of the edentates the subclavius arises from the first rib, and is inserted into the whole extent of the upper border of the acromion process by a flat tendon, and becomes continuous with the fascia over the supraspinatus and the head of the humerus.

It is split into two portions by the strong coraco-clavicular ligament. In orycteropus capensis the subclavius arises from the manubrium and the first rib, at its junction with the sternum, and in part by a slight prolongation of its fibres from the aponeurosis of the rectus.

It is inserted aponeurotically, along the upper border of the acromial half of the clavicle, into the acromion and supraspinatus fascia.⁴ In chlamydophorus truncatus it arises from the first rib, and is inserted into the coracoid process, acromion, and the acromial end of the clavicle.⁵ In ai it is inserted into the clavicle and coracoid process.⁶ The subclavius is absent in manis, myrmecophaga jubata, and some others. A retro-clavicularis is present in chlamydophorus, and arises from the upper surface of the first rib, near the sternal end, and is inserted into the acromion, process and supra-spinatus fascia and coraco-acromial ligament.⁵

In ruminants a sternoscapular muscle arises from the manubrium, and is inserted into the scapula.³ In the hippopotamus the subclavius is expanded upon the supra-spinatus at its insertion, forming a ster-

nocosto-scapularis. In the pig it reaches the radial tubercle of the humerus.¹

In the porcupine the subclavius arises from the costal portion of the first rib, has a slight attachment to the scapular extremity of the clavicle, and is finally inserted into the spine of the scapula, the supraspinous fascia, and by this to the deltoid, and is extended over the supraspinatus to the humerus.²

In the guinea-pig the subclavius arises from a small surface on the presternal pro-osteon, and from the cartilage of the first rib, exteriorly, to which latter point of origin the epicoracoid has coalesced with the vertebral rib. Some of its fibres are inserted into the coraco-clavicular ligament and some into the clavicle, but it receives fibres also from the clavicle. The muscle is then inserted into the acromion (anterior border), and with the deltoid some fibres become continuous.³

In the cheiroptera the subclavius arises from the first rib, and is inserted into the clavicle.⁴

The following table represents the varieties, with an origin from the first rib, rib and manubrium, and rectus, or precoracoid and scapula. It is inserted into—

- (1) The suprascapula and scapula.
- (2) The humerus.
- (3) The coracoid.
- (4) Outer end of clavicle and spine of scapula.
- (5) Acromion, supraspinatus fascia, and humerus.
- (6) The scapula, with an origin from the sternum.
- (7) Receives fibres from rectus.
- (8) Radial tubercle of humerus.
- (9) Spine of the scapula and humerus.
- (10) Coraco-clavicular ligament, clavicle, and acromion.
- (11) Clavicle only.

Comparing the varieties found in man with these, the subclavius has occasionally an attachment to the clavicle, coraco-clavicular ligament, and coracoid process. It may be inserted into the clavicle, coracoid process, and upper border of the scapula, and may at the latter place be intimately connected with the supraspinatus fascia.

A condition, very similar to that of ruminants, was observed by Mr. Wood, and recorded by him many years ago. The subclavius may be absent; of this I have met with two cases in ninety subjects dissected during the present session. Absence of this muscle was observed by Prof. Gruber.

If the varieties of the omohyoid be placed side by side with those of the subclavius, it will be seen that, first, as far as the origin is concerned, there is evidence of a connexion with the rectus. In the case of the former the anterior belly is inseparably united with the ventral muscle in some lower forms, and occurs as a not infre-

quent variety in man, so that in these the posterior belly must be regarded as a muscle radiating from the rectus, and, in the case of the latter muscle, a variety is presented in the wombat, where the fibres are (in part) continuous with the rectus. An origin of the omohyoid, on the other hand, from the sternum is not, so far as I know, on record; and an example of a sterno-scapular muscle, which, I think, must be regarded as belonging to the sternohyoid set of muscles, I shall give later on. The insertions of the omohyoid and subclavius present, however, many characters which show a definite relationship between these muscles. Each muscle is inserted in some of the animal forms into the clavicle, scapula, coracoid process, and humerus. What in man is a normal attachment of the omohyoid, is an aberrant attachment of the subclavius, and the omohyoid is attached to the under surface of the clavicle in a large percentage of cases. Six cases were recorded in ninety subjects during the present session (1880–81).

I shall now give some varieties of these muscles. Two of the subclavius are recorded with accompanying variation in the attachment of the omohyoid.

The first case is that of a costo-scapular muscle, differing but little from the cases of Theile and Wagner. That it was a true subclavius will be easily seen from the description.

1. In a female subject, aged forty-five, on both sides of the body a muscle arises from the cartilage of the first rib by a tendon one and a half inches in length; this is continued into a round fleshy belly which passes beneath the clavicle, to which it is attached by a firm fascia, over the subclavian and suprascapular arteries and brachial plexus, and is inserted into the upper border of the scapula for one inch, extending forwards from the superior angle. The muscle is supplied by a branch from the fifth and sixth nerves of the brachial plexus.

The omohyoid arises from the under-surface of the clavicle for the extent of one inch at the junction of the middle and outer thirds of the bone; it passes upwards and inwards and unites with the sternohyoid. Below the point of union is situated a tendinous inscription in the omohyoid, from the inner extremity of which a fibrous band passes inwards to the sternohyoid, where it is prolonged into a tendinous inscription less marked than that of the omohyoid. From the arch so formed fleshy fibres pass up to the conjoined sternohyoid and omohyoid, filling up the triangular interval by a thin fleshy stratum. The fibrous band, which was one-tenth of an inch broad, has been referred to by Professor Turner in his paper.

2. The second example occurred in a male subject, aged fifty. The trapezius is inserted into the outer two-thirds of the clavicle on each side; on the right side the external jugular vein passes through a foramen in the muscle close to the clavicle, and the supraclavicular nerves pass forwards through the same foramen. The

¹ Observations on Myology.

² Rolleston. Loc. cit.

³ Galton. Loc. cit.

⁴ Macalister. Trans. Roy. Soc. 1872.

omohyoid is attached to the upper border of the scapula from the superior angle to the notch, to the ligament over the notch, and to the base of the coracoid process; it is further attached to the outer half of the clavicle. The external jugular vein and supraclavicular nerves pass beneath a tendinous arch close to the clavicle, to which some fibres are attached. The muscle is inserted into the hyoid bone superficial to the sternohyoid. A cleidohyoid muscle arises from the inner third of the clavicle for the extent of one inch, is separate from the sternohyoid in all its extent, and is inserted into the hyoid bone above that muscle. On both sides a supraclavicularis is present, arising from the manubrium beneath the sternomastoid; it is inserted into the clavicle between an anterior and a posterior layer of the sternomastoid.

The interest attaching to this case is due to the many irregularities. The individual varieties have been observed by many anatomists. The attachment of the omohyoid superficial to the sternohyoid is the fact which I shall make use of.

3. In a male subject, aged forty-eight, on the left side of the body the omohyoid has the normal origin. Above the middle of the clavicle it divides into two parts; the upper is connected with the anterior belly by means of a tendon, and this belly of the muscle is closely connected with the sternohyoid.

The lower division, half an inch broad, is inserted into a more than usually strong tendinous inscription in the sternohyoid. The place of insertion is on the anterior aspect of the muscle. A muscular fasciculus is given by this muscle to the sternothyroid, the outer border of which it joins.

4. Instances are on record where the omohyoid presented a double belly at the anterior and posterior part. In a male subject (left side) this muscle arises from the scapula at the usual place, and is inserted into the hyoid bone. So far the muscle presents no unusual features, but for an extent of three inches extending on both sides of the tendinous inscription the muscle is double; each part resembles a normal omohyoid.

5. The last variety in this connexion to which I shall refer is the case of absence of the anterior belly. This variety is rare, as Professor Macalister did not meet with it once in 600 subjects. The variety occurred in a female subject, in which the omohyoid of the right side presents an anomaly somewhat similar to that recorded by M'Whinnie. A portion of the outer fibres passes over the sternohyoid near its insertion, over the hyoid bone and beneath the mylohyoid, and then enters the geniohyoid. A portion of the sternohyoid crosses beneath this bundle and is continued into the hyoglossus. On the left side of the head and neck the omohyoid arises from the scapula and terminates in a fibrous band in front of the carotid vessels. This divides into two; both pass upwards; the inner is inserted into the os hyoides, the outer is lost in the cervical fascia, with

which both are in close connexion.

These varieties point to the fact that the anterior belly of the omohyoid, usually distinct in the case of man, lying side by side with the sternohyoid near its insertion, and inserted border to border with it, and so far may be understood as obtaining its substance, not from the rectus, but from the prolongation of the lateral internal oblique layer, as distinguished from the mesial part; yet the variety given under No. 2 shows that the anterior belly may have an intimate connexion with the: superficial part and not the external part. And No. 5 shows, as, indeed, other varieties, that the anterior belly may be connected with the posterior part of the prolonged rectus. Variety No. 4 is another illustration bearing on this point—a portion of the omohyoid is inserted into the anterior part of the tendinous intersection of the sternohyoid. Unless a portion of the anterior belly be considered as absent in this case, we must regard a part of the sternohyoid above the intersection as portion of the omohyoid that has coalesced with the sternohyoid, but a third assumption is possible—namely, that the fibres of continuation are to be sought in the part below the intersection. In case, then, these varieties point to the fact stated by Prof. Henle that the anterior belly corresponds to the sternohyoid, and should be regarded as the analogue, or, to go a step further, as a differentiated part of the sternohyoid mass, this differentiation can be easily accounted for. The separation of the cleidohyoid, as given in No. 2, from the more deeply placed sternohyoid, can be explained on the same principle as the separation of muscles into layers in the limbs and elsewhere, and such an interpretation is rendered almost certain by the fasciculated varieties met with in connexion with the omohyoid.

The division of the muscle given above was as perfect as the ordinary separation that exists between the sternohyoid and the omohyoid; and the muscle shreds that so frequently exist between the omohyoid and the sternohyoid is additional evidence bearing on this point. On the whole, therefore, the varieties met with point to the fact that the anterior belly of the omohyoid should be regarded as a portion of the sternohyoid (at least in man), and that the tendinous intersection of the central mass represents the point at or below which the separation takes place. That the breadth of the tendon of the omohyoid to some extent depends upon the extent of the original connexion of the posterior belly with the mesial mass. Its length is probably due to a variety of circumstances—the extent and firmness of the fascia investing it, the length of the muscle, and the angle of junction. The first and last because they affect its action, and the second, conjoined with either of the former, would serve to increase its length. The absence of an anterior belly is attributable, without doubt, to a solution of the connexion with the mesial mass, or to its

original weakness.¹

So far, then, as the omohyoid can be regarded as composed of a sternohyoid portion and a recto-scapular portion, the posterior belly is similar in its anterior connexions with the portion of the subclavius met with in phascolumys and orycteropus, which in these creatures is connected with the rectus or its expansion; and the similarity in the attachments of the muscles posteriorly I have already mentioned. The nervous supply of the two muscles is different, and is apparently an argument against the homology of the muscles, if there were no other; but the fact that the omohyoid is intimately connected with muscles supplied by the nerves in the tract of the descendens noni, and other instances, such as that of the levator anguli scapulæ, and the serratus where the nervous supply is different, at least frequently—the former muscle, no doubt, sometimes receives a branch from the fifth; but a branch from the third is a very constant nerve to this muscle—furnish reasons for this difference in nervous supply.

The supraclavicularis, originally described by Professor Gruber, has an attachment at the inner and outer end of the clavicle. Tendinous at each extremity and fleshy at the middle, it has been considered by the anatomist who first described it as a tensor of the fascia, and by him regarded as the representative of the fibrous band which one sees occasionally above the clavicle giving attachment to the trapezius. The muscle occurred twice during the present session in the anatomical rooms, and in one case corresponded exactly with the description given by Gruber. This muscle was supplied in the case to which I refer by the descendens noni. A muscle such as this supplied by the descendens noni seems to show that it does not correspond to the fibrous band situated above the clavicle, but must be regarded as a muscle of a deeper layer—namely, of the layer to which the depressors of the hyoid bone belong. It would more appropriately be referred to the fibrous band mentioned in one of the notes given above. Such a muscle, then, might be regarded as a portion of the internal oblique layer which lost its attachment to the sternohyoid band and acquired an external attachment to the clavicle at a place where a cleidohyoid muscle is sometimes found. That the muscle must be regarded in this light is, I think, shown by the following variety, which, as far as I know, is new:—

In a female subject, aged seventy-eight, on the left side of the head and neck the omohyoid is attached to the outer third of the clavicle for one inch, and is prolonged to the upper border of the scapula where it is attached to the ligament over the notch, as also to the bone. Arising in this way the omohyoid passes it up-

wards, and is inserted into the hyoid bone. A faint line which extended transversely across the muscle indicated the line of division of the muscle into two parts. The subclavius on this side has a slight attachment to the clavicle externally (half an inch). It is, however, attached by a slip to the coracoid process, and by a band to the upper border to the scapula beneath the omohyoid. The arrangement resembles that of Böhmer's case, cited by Professor Macalister.

On the right side a sternoscapular muscle arises from the posterior surface of the sternum in this way:—From the anterior surface of the tendon of origin of the sternothyroid tendinous fibres are prolonged upwards and outwards. These are reinforced by fibres arising from the anterior surface of the sternothyroid, and which have a transverse direction above the tendon and below the tendinous intersection of the same muscle. From the band so formed external to the sternothyroid a muscular belly arises, which passes outwards above the clavicle over the subclavian artery and brachial plexus, and terminates in a tendon two inches and a half long, which is inserted into the upper border of the scapula and ligament over the notch for the extent of one inch. A small band passes down to the outer third of the clavicle, and a portion of the fibres is continued into the supraspinatus fascia. The breadth of the tendon of origin is one inch and a quarter; the breadth of the muscle about four lines. The omohyoid has a slight origin from the upper border of the scapula, but is attached to the upper border of the outer tendon of the sternoscapular muscle for its whole length. The muscle passes upwards and inwards to the hyoid bone, and is connected with that muscle so closely, three inches below its insertion, that it cannot be easily separated. Below the point of union a muscular fasciculus from the omohyoid joins the sternohyoid. A tendinous inscription is present above the middle of the omohyoid, oblique in direction, and very faint. The sternoscapular muscle is supplied by a branch of the descendens noni which enters the muscle near its inner tendon. The sternohyoid of the right side has only a clavicular origin, so that, in reality, it is not properly designated by this name. On the left side the muscle has both a clavicular and sternocostal attachment.

This muscle has much in common with the supra-scapularis proprius and the retro-clavicularis, and I think these two muscles may be considered varieties of the foregoing. Dr. Macalister has already stated as his opinion that the muscle described by Mr. Lawson Tait is to be regarded as a variety of the supra-scapularis. To the same set the sterno-humeral muscle of Gruber may with justice be referred. The position of the supraclavicular nerves in this case seems at first sight to show that the sternoclavicular muscle has a significance different from the supraclavicularis, for in Prof. Gruber's example and the two instances referred to, these nerves passed beneath, whilst the same nerves passed in front

¹ Dr. Whitla, of Belfast, has told me of a case where the anterior belly was displaced by a small round tendon on both sides. It occurred in a person who had worn a trachea cannula for forty-three years.

of the sternoscapularis; but this objection loses its importance when we consider that the descending nerves of the cervical plexus sometimes pierce the clavicular origin of the omohyoid or even the clavicle, or may pass under a tendinous arch into which the latter muscle is inserted.¹

The supraclavicular nerves in this example passed over the omohyoid and the sternoscapular muscle. The relations of the origin to the sternothyroid and the insertion of the omohyoid, together with the fact that the muscle has the same nervous supply, show that it belongs to the lateral ventral muscle.

The connexion with the posterior part of the omohyoid seems to show that these muscles are to be regarded as parts of the same lateral muscle band; and the connexion of the sternoscapularis with the sternum internally, the clavicle and scapula externally, shows that it is a serial homologue of the subclavius. The posterior belly of the omohyoid must, I think, be regarded as homologous with the subclavius. The reasons for this conclusion may be briefly stated thus:—

(1) The origin of the subclavius is closely connected with the rectus in some animals. Wombat, *orycteropus*. The posterior belly of the omohyoid passes into the mesial layer prolonged from the rectus, as a permanent condition in *cryptobranch*.

(2) The nerves of the limb separate equally the subclavius and costo-coracoids equally with the omohyoid from the serratus or costo-scapular group.

(3) The aberrant supraclavicular muscles present an origin and insertion similar to the subclavius, and resemble closely the omohyoid in their attachments, relations, and nervous supply.

(4) The extensive clavicular attachment of the omohyoid in certain of the animal series can be explained as a part of the attachment of the recto-clavicular muscle—the inner surface, in some cases, being part of the rectus prolongation.

(5) The omohyoid is bound down to the clavicle so closely in many cases as to completely obliterate the subclavian triangle—in 13 out of 373 subjects (Turner, loc. cit.); and the same arrangement occurs when the subclavius takes origin from the scapula, as in case given above.

J. Walton Browne M.D.

The Ninth Meeting of the Society was held upon Tuesday March 22nd 1881 at eight o'clock p.m.

Present, Dr. J. W. Browne in the chair, Drs. S. Browne, Esler, Smyth, McCaw, Wales snr., Wales jnr., Workman, Fagan.

Dr. Dunn was unanimously elected member of the Society

The President then exhibited a patient in whom the

¹ Krause. Die Nervenvarietäten. During the present session I have recorded three instances where a single branch of the descending nerves perforated the clavicle.

median nerve was divided; and the brachial, ulnar, radial and common inter-osseous arteries were ligatured consequent upon a punctured wound of the arm.

He then exhibited a very interesting specimen of diseased kidney, microscopic sections of which were made by Dr. Workman demonstrating it to be of tuberculosis nature.

He finally showed some casts removed from the urethra, concerning the nature and origin of which differences of opinion were expressed.

Mr. Fagan exhibited a case of wrist joint disease treated by drainage and give details of same.

W. Whitla, M.D., Chairman

April 5th 1887

The Tenth Meeting of the Society was held upon Tuesday 5th April 1881.

Present, Dr. Whitla in the chair, Dr. Harkin, Dr. Fagan, Mackenzie, Kevin, Dunn, Johnston, James Moore, Stewart, J. W. Browne, McKeown.

Dr. Fagan exhibited a specimen of elephantiasis of the labia removed by him. The tumour was very large and had weighed about 30 lbs. Dr. Fagan also gave some particulars of the case.

Dr. Harkin thought that a cast ought to be taken of the tumour as its character would change much in keeping.

Dr. Johnson thought he had seen a tumour almost as large on the neck of a man under the care of Dr. Vesey in the Union Infirmary.

Dr. Moore wished to know if there was any coloured blood in the patient and thought that the tumour should be preserved in a museum.

The chairman (Dr. Whitla) considered that there was much risk throwing all the blood from so large a tumour into the general circulation as it would give too much work to the excretory organs.

Dr. Harkin then read a paper on rheumatism and its cure.

Paper:¹ I think it will be generally admitted that the subject of acute rheumatism, as far as its pathology, ætiology, and treatment are concerned, is still in a very unsettled condition, and that the position assigned to it in the nomenclature of disease is unstable and unsatisfactory. Our early nosologists, *Sauvage* and *Vogel*, gave it a place among the class *Dolores*; *Mason Good* in the class *Hæmatica*, order *Phlogotica*; *Cullen* among the *Pyrexia*, order *Phlegmasia*; *Dr. Farr* some forty years ago believing that acute rheumatism was due to a materies morbi introduced into the body, which, after an indefinite period, leavened the whole mass of the circulating fluid, included it in the list of zymotic diseases in the same category as *scarlatina*, *cholera*, and *erysipelas*; later on the *College of Physicians* classed it

¹ [Dublin Journal of Medical Science, 1881, v72, p296.]

with the constitutional diseases, along with Scrofula and Purpura.

Among our writers on systematic medicine, Sir Thomas Watson says that “rheumatism is a blood disease, that the circulating fluid carries with it a poisonous material, which, by virtue of some mutual or elective affinity, falls upon the fibrous tissues in particular, visiting and quitting them with a variableness that resembles caprice, but is ruled no doubt by definite laws to us as yet unknown;” while Ziemssen, taking into account no pathological relations or affinities whatever, simply from a regional point of view, established a class for itself, grouping with it gout, arthritis, rickets, and mollities ossium, under the heading of “Diseases of the Locomotive Organs.” The importance of a correct nosological and pathological definition of acute rheumatism cannot, in my mind, be overrated, as it is to a great extent on those bases that its ultimate cure must depend. Senator says “its treatment has varied with our theories concerning its pathology, since rational therapeutics (really or apparently in harmony with accepted views on pathology) were substituted for traditional empiricism.”¹ Further on Senator says in forcible language “that no remedy has up to the present time established its claim to universal favour—none has been discovered to possess undoubtedly specific virtues, to be capable of summarily arresting the disease under all circumstances.”

The statement of Fuller is as applicable to-day as when announced a quarter of a century ago—viz., “that each and every plan of treatment which has been hitherto proposed is regarded by the profession as unsatisfactory.” And according to Garrod, “further observation and experiment are required before we can arrive at any satisfactory conclusion with regard to its pathology.”²

Should the existence of this regrettable state of affairs be questioned, one has only to think of the heterogeneous list of remedies so opposite in their nature recommended for the cure of this painful disorder—acids and alkalis; mercury and mint water; venesection and quinine; hot blankets and the cold bath; the hypodermic injection of morphia into the joints and the blistering plan of Davies; subcutaneous injections of cold water and of carbolic acid; cotton wool and icebags to the swollen joints and spine; opium and atropia; tartar emetic and colchicum; aconite and veratrum viride; and, finally, the most fashionable and most disappointing of all—salicin, salicylic acid, and its compounds.

What is most strange is the fact that each of these remedies has for its sponsors most learned and able authorities who can point to apparent cures of this disease, although without being privileged to claim any great numerical advantage over others. We wonder indeed at the toleration of such diverse and heroic rem-

edies, and are reminded of the observations of Dr. Clutterbuck, who said that, “though ligamentous inflammation does not yield so readily as some other inflammations, it bears almost all kinds of treatment with impunity, and at last often subsides spontaneously, the disease seeming to wear itself out.”

Salicin and its compounds deserve more than a passing notice. After being experimented with in Germany, it was introduced to the profession in this country by Dr. Maclagan, of Dundee, who assured us that “it seems to arrest the course of the malady as effectually as quinine cures an ague or ipecacuanha a dysentery; that given sufficiently early and in sufficient doses it prevents cardiac complications, and that its free administration is the best means of staying their progress after they have occurred.” Now, were these promises fulfilled in practice, we might rest on our oars, having been thus provided with the true specific for this intractable disorder. But what does experience testify? Five years have now elapsed (March, 1876) since its advent was so loudly heralded, and what are the fruits? It is certainly entitled to the character of a most potent antipyretic, and, inasmuch, is capable of controlling one of the many distressing symptoms of rheumatic fever, but at what cost to the patient? In my own experience it has proved most deceptive and dangerous. Of salicylic acid and its salts, Senator says that in a considerable proportion of cases “they give rise to vertigo, headache, tinnitus aurium, and deafness, nausea, and vomiting after every dose; profuse sweating, great weakness, with a peculiar eruption on the skin; more rarely the symptoms assume a dangerous complexion, violent delirium, albuminuria, great prostration, with pallid skin and feeble pulse, ushering in fatal collapse, and these results have been observed after the administration of perfectly pure samples of the drug. He thinks highly of salicin, being fundamentally the same as salicylic acid, and that it does not give rise to any of the disagreeable or dangerous accidents common after the salicylic acid and the salicylates.” So far Senator. However, in *The British Medical Journal*, February 12th, 1881, Dr. Charteris, of Glasgow University, gives the result of his experience of 80 cases in which salicin was prescribed. He says—“In uncomplicated cardiac cases it will lower the temperature in forty-eight hours; if the temperature be not lowered in that time, in all probability the heart is affected, and in that case the medicine should be countermanded, for then it will in no way diminish the fever.” And Dr. Curnow, Assistant Physician to King’s College Hospital, in *The Lancet* of Nov. 18, 1876, gives the particulars of a case in which, after having given the salicin in large doses, so much as 800 grains in five days, prior to the appearance of the friction sound, “the result was the absence of any relief whatever, the supervention of a very acute pericarditis, the powerlessness of this remedy against the complication and the attendant fever, the appearance of the

¹ Ziemssen. Vol. XVI., p.59.

² Reynolds. Vol. II., p.904.

friction sound, a tedious recovery and prolonged convalescence.”

Moreover, in two very elaborate papers communicated to the Clinical Society of London by its President, and published in *The British Medical Journal*, 9th May, 1880, Dr. Headlam Greenhow states that in 10 cases of acute rheumatism in which he gave salicin alone, and in 50 cases in which salicylate of soda was administered, similar unhappy and perilous results were developed during their use, often requiring stimulants to restore the heart's action. His conclusion is “that these agents could not be regarded as in any respect specifics in the treatment of rheumatic fever. In all the most acute cases the relief derived from the medicine passed away soon after it was intermitted, and a relapse, sometimes several relapses, took place. Excluding mild cases and deaths, out of 32 remaining there were twenty-one relapses; in 7 one; in 9 two relapses; in 2 three relapses; in 2 four relapses; in 1 five relapses.” Dr. Headlam Greenhow says, in conclusion, “that the complications were not less frequent, the condition of the patient was worse after recovery, and the length of time the patient was disabled was longer than under other modes of treatment. Of those 37 cases they were on an average fifty-seven days in hospital” (forty-two being, as we all know, the normal period, even under the Nihilistic treatment). No stronger condemnation could possibly be pronounced against any vaunted remedy. He concludes that “the pain and distress of the patients were undoubtedly for a time greatly relieved; he feared that the marked weakening of the first sound of the heart present in many when salicylic acid was given indicated the exertion of an influence on the muscular structure which might not pass entirely away when the treatment was suspended. Its prolonged use was likely to prove injurious when the heart was affected.”

That salicin and its compounds act as powerful depressants of the heart's action no one will likely question after the above statements. Salicin never acts therapeutically until its physiological or rather its toxic influence is first induced. Indeed, if we examine closely into the modus operandi of this and the other remedies previously referred to, we shall find that the measure of their beneficial agency in the relief of individual symptoms of acute rheumatism is exactly the extent to which they operate directly or through the medium of the nervous system on the heart itself, thus arriving by different routes at the same goal, just as in olden times all roads were said to lead to Rome.

As my object, however, is purely practical, and not merely to dilate upon the insufficiency of accepted remedies, I shall proceed to relate a number of recent cases, as observed by myself and some of my professional brethren, in which by a simple remedy, and practically without the administration of any medicine, the cure effected in almost every case was at once

rapid, simple, and complete.

Case I.—Acute Rheumatism.—On 24th October, 1879, I visited Sub-constable H., R.I.C., aged thirty, married. He had a rigor three days previously, followed by pains, especially in the left knee and thigh, which were red and swollen.

25th.—Pains had extended to right knee, to both ankles and shoulders.

26th.—Left elbow also engaged; perspiration acid and profuse; urine scanty and loaded with urates.

27th.—State unchanged. Ordered an opiate at bedtime. He had been laid between blankets and his joints wrapped up in flannel and cotton wool.

28th.—Had not slept for a week; at 1 p.m. his temperature was 102°, pulse 108; no improvement; no cardiac affection observable; at that hour I applied a blister 4x3 inches over the region of the heart, ordering its removal in eight hours, and to be replaced by cotton wool.

29th (noon).—Found the patient completely relieved; countenance cheerful; pulse 90, temperature 98°; tongue clean; thirst diminished; perspiration gone; urine copious and clear, and from being on the previous day paralysed in every joint and quite helpless, he was able without pain to flex and extend every joint, and to sit up in bed with ease. He stated that he began to feel relief at 6 p.m. on the previous day, five hours after the application of the blister; that soon after he fell asleep for the first time for many days, and that having occasion to rise during the night he walked unaided across the room, and only remembered his rheumatism after returning to bed. On examining the joints every trace of redness had gone, and the swelling was scarcely perceptible; the joints could be grasped firmly without pain. He then stood up and walked across the floor without any undue effort.

29th and 30th.—Still improving; pulse 90, temperature 98°; swelling and pain absolutely gone from every joint; heart free.

Nov. 1.—Pulse 64, temperature normal; convalescence complete, and my visits ceased. A week after he walked to my residence on a frosty day without any injury, and he soon after returned to duty.

Case II.—Subacute Rheumatism.—On 16th December, 1879, I visited Mrs. B.; she had been confined fourteen days previously; child at nurse; had a shivering on 11th; next day both hands and the left shoulder became painful and swollen; pain increased at night; sleepless for five preceding nights. On examination I found both hands swollen and powerless; all the carpal, metacarpal, and carpo-phalangeal joints were implicated; perspiration profuse; urine scanty and high-coloured. This was her third attack, having been ill for thirteen and sixteen weeks in first and second attack. In this case I did not prescribe a particle of medicine, but applied a blister over the cardiac region.

Calling next day, I found the patient sitting up in bed.

Ulster Medical Society
Session 1880–1881
President John Walton Browne

Despite the pain of the blister she had slept all night. The perspiration had left, *pari passu*, with the pain. The right hand had already regained its power, the fingers were quite free, and in three days after the left hand, which had been most swollen, was quite relieved. I paid her but two other visits, and on the last of which I was gratified to find her down stairs, nursing her baby and perfectly able to take charge of it. My friend, Dr. William Aicken, saw this patient once with me.

Case III.—Acute Rheumatism.—J. F. R., aged fourteen, tall and stout, had a rigor on 6th April, 1880, followed by pains in right and left knee and ankles. I visited him on 9th; found him lying on his back, unable to move from the swollen condition of his joints, his elbows especially. Pulse 88, temperature 101°; urine clear but scanty; perspiration plentiful.

10th.—Condition unchanged.

11th.—Still sleepless, although he had an opiate on previous night; urine now highly acid, with copious deposit; heart pulsating violently, with distinct systolic apex murmur. Dr. Whitla, who examined the patient this day, coincided in the diagnosis. In his presence I applied a blister, *regioni cordis*, to be retained for eight hours.

12th.—Found the patient sitting up and relieved; he had slept soundly all night after the removal of the blister, and had got up unaided to the night chair; urine again clear; pain and swelling reduced in all the joints, which he could flex without trouble. Pulse and temperature unchanged.

13th.—Still progressing; slept well; urine clear; sweating gone; found him again sitting up and anxious for removal into next room. Pulse 68, temperature 99°.

14th.—Temperature 98°, pulse 60.

16th.—Temperature normal, pulse 56; all traces of swelling gone, and convalescence complete; he had taken in all 10 grains of opium. Dr. Whitla watched the progress of this case with me. The pulse and temperature in this case fell so low that I had to order stimulants. Fourteen days after all trace of cardiac symptoms had departed.

Case IV.—Subacute Rheumatism.—Miss L. V., aged ten years, had a rigor on 17th April, 1880, followed by great muscular pains and general malaise, succeeded by urticaria; both ankles then became painful, red, and swollen, and also the right knee.

I saw her upon the 19th; she was then in bed, and unable to move from the severity of the pains; pulse 88, temperature 101°; urine scanty, clear, of acid reaction; bowels confined; perspiration very free; increased palpitation of heart and well-marked apex systolic murmur. Ordered a laxative.

19th.—Fever and thirst increased; had not slept. I applied a small blister over the region of the heart for four hours. The joints had been previously enveloped in cotton wool.

20th.—Pain and swelling of joints much less; had

slept well; perspiration diminished; urine muddy with pink deposit; tongue clean; soft murmur over apex. Pulse 86, temperature 100°.

21st.—Pains all gone; pulse 84, temperature 99°; slept well; appetite restored.

22nd.—Slight recrudescence of pain in right knee, which is stiff.

23rd.—Pain and swelling gone from knee; pulse 80, temperature normal; blister almost healed; much stronger.

24th.—Convalescent; to be removed to another room. The cardiac symptoms did not quite subside for a period of fourteen days.

Case V.—Acute Rheumatism.—I visited A. S., aged thirteen, on 6th November, 1880, and found her suffering from pains in every joint, this being her third attack of acute rheumatism.

She was an inmate of an industrial school, and attributed her illness to a long walk on 1st Nov., a very frosty day. She was removed to a newly-plastered infirmary, on account of overcrowding, where I found her along with L. G., the subject of the next case. Pulse 112, temperature 103°; her heart beating tumultuously, with systolic murmur at apex; 15 minims of *tr. opii* were given at bedtime.

7th.—Next day no improvement.

8th.—Before proceeding to treatment I requested my friend, Dr. Esler, to accompany me. Pulse was then 120, temperature 103°; face flushed, and she was crying loudly for something to cool her. I then applied a blister over the heart for six hours, to be dressed as usual with cotton wool.

9th.—Visited with Dr. Esler; our report was—pulse 118, temperature 102°; painful symptoms much abated; bruit softer; ankles free; shoulder better; can flex knee freely; she walked across the room and returned without difficulty; to-day friction to-and-fro sound first appeared; applied a blister over the sternum.

10th.—Pulse 96, temperature 99°; pain absent everywhere except on left hip; urine clear; slept well.

11th.—Pain of hip gone; pulse 100, temperature 102°; pericardiac trouble subsiding, as well as apex murmur.

12th.—Dr. Whitla joined Esler and myself; his report was—“No affection of any joint whatever, nor is there pain or tenderness anywhere except over the cardiac region; pulse 90, temperature 101.5°; a loud friction murmur over the entire area, masking a feeble endocardial murmur near to the left nipple.”

13th.—Pulse 86, temperature 99.5°; cardiac sounds still loud; no further articular troubles; further signs of effusion, with prominence of left side.

14th.—Area of dulness less; temperature 98°, pulse 72; friction sound less; bruit still perceptible; crepitation at base of lung and left axillary region. A mustard poultice to be applied.

15th.—Pulse 60, temperature 96°; countenance pale;

extremities cold. To have 2 oz. wine in the day and hot water bottles to feet.

16th.—Pulse 72, temperature 97°. 4 oz. wine.

17th.—Found her sitting up at lunch in bed.

18th.—Improved in every respect and proceeding to convalescence, when an inexperienced nurse stripped her at the fireside, exposed her to the cold air of the room, and splashed her over with tepid water, when she immediately took a shivering, and all the cardiac symptoms returned with violence. A fresh blister, however, and a week's rest in bed served to restore her health, and before the end of the month of November she was quite well and free of all cardiac and articular trouble.

Case VI.—Acute Rheumatism.—L. G., aged fourteen; first attack; resembled case No. V. so much that it need not be pursued from day to day. She was exposed to the same chill while walking on 1st November, lay down about the same time, had the same cardiac ailments, and about the same time recovered her strength. She was then maltreated in the same way by exposure and bathing in the newly-plastered room, took a rigor again, was again attacked by the cardiac affection, but was not so fortunate as S., for after getting over all acute symptoms there still remains a persistent murmur at the apex of the heart. My friends, Drs. Esler and Whitla, saw this child along with S., she being in the next bed and same room. She was up and going about on 4th December.

Case VII.—Subacute Rheumatism.—On Nov. 25, 1880, I was called to a religieuse, Sister M., in her convent.

She was anæmic and of hysterical and nervous temperament. She had sore throat, insomnia, general muscular pains, and profuse perspiration. I prescribed for those symptoms, but on 1st December they became more pronounced; pain and swelling of the joints of the upper and lower extremity and acute pain in the præcordial region, increased by respiration, now appeared.

2nd and 3rd Dec.—Was much worse; in addition severe headache, flushed eyes and countenance ensued, and sleeplessness continued. Pulse 98, temperature 100°. I then applied a blister over the heart for six hours.

4th.—Found the patient cheerful and smiling, with clear eyes, face pale as in health, headache quite gone, perspiration had ceased, and all the joints were free from pain and swelling and capable of motion; she could turn in bed without assistance, and had slept soundly; pulse 72, temperature normal; kidney secretion plentiful and clear.

5th.—Improvement proceeding; appetite restored; she rose in three days after, and on 10th December removed into another room, and my visits ceased.

Case VIII.—Subacute Rheumatism.—Sister M. A., in the same convent, while out on visitation on 6th March, 1881, felt fatigued; had a shivering next day, followed

by sore throat, general fever, and muscular pains. On 11th her left knee became red, swollen, and painful; then the right knee and elbow, then right ankle and both wrists became engaged. At this time the heart's action became irregular, with frequent intermissions, and an acute pain was complained of in the interspace between the fifth and sixth ribs, left side. Perspiration very free.

19th and 20th.—Symptoms more pronounced, and on 21st I applied a blister at 3 p.m. over the heart, the temperature being 100° and pulse 84. Next day she declared herself quite well; had found relief at 3 a.m., twelve hours after the application of the blister; she could now flex and extend all her joints freely; swelling and pain almost gone; perspiration much less; kidneys acting freely. Pulse 72, temperature normal.

24th.—Improvement continued; sleep and appetite had returned; was able to rise, and complained of nothing except five or six spots of erythema nodosum, the size of a penny, that had appeared on her limbs; they were very troublesome, but yielded at last to free doses of fluid magnesia.

The next five cases are kindly contributed by my friend, Dr. J. Walton Brown, Royal Hospital, Belfast.

Case IX.—Subacute Rheumatism.—Miss C. B., aged twenty-four, ill since 10th February, 1880, was seen by me on 16th; she took ill with a sore throat and general pains, especially in her knee-joints; she perspired freely on 12th and felt better; her hands and wrists now became swollen and painful, so as to prevent sleep; the pains continued in all the joints, and she became quite helpless. When I visited her both hands and wrists were much swollen, and she could not bear the slightest pressure; had pain in the præcordial region, with slight mitral murmur; pulse 120, temperature 103°; evidently suffering from acute rheumatism. I prescribed no medicine, but following out the treatment suggested to me by my friend, Dr. Harkin, I applied an emplastrum lyttæ, 3x3 inches, over the heart for twelve hours. On my next visit sixteen hours after the application of the blister, I found all pain gone from the hands except when she moved them, and from the other joints; all swelling had entirely subsided; the pulse had fallen to 88 and temperature to 99°. Next day I put her upon a mixture of potass, bicarb. and tr. opii. She was then able to leave her room, and upon 26th February she left for the country. Certainly the effect of the blister in this case was marvellous, the pains ceasing, pulse and temperature coming down, and all swelling subsiding in sixteen hours after the application of the blister.

Case X.—Subacute Rheumatism.—Miss A., from the West of Ireland, was seen on 14th February, 1881. She complained of weak vision and general debility, and was very anæmic. I did not visit her again till 19th March, when I found her labouring under an attack of

subacute rheumatism. The pulse numbered 90 and temperature 99.4°. The wrists, knee, and ankle-joints were very tender to the touch. Ordered a blister, 2x2 inches, to be applied for twelve hours over the cardiac region and cotton wool around the joints; milk diet. Called two days afterwards, and was surprised to find my patient sitting up and all pains gone. She felt very weak, but under treatment was quite well upon 1st April.

Case XI.—Subacute Rheumatism.—Miss M. S., aged four years, was seen by me upon 6th March, 1881. She was suffering from an inflamed throat, with glandular enlargement in the neck. I prescribed the routine treatment, and did not see her again till 11th March. When I visited her I found her ill with acute rheumatism; the wrist and knee-joints were swollen and tender; pulse 120; skin perspiring; she had not slept on previous night on account of the excessive pain. The temperature was not taken.

Applied a blister, 2x2 inches, over the cardiac region, to remain for ten hours; cotton wool to the joints affected. No abnormal cardiac sound could be heard. Next day (12th March) all pain gone from the wrist and knee-joints. The child had slept some hours after the blister was taken off; the pulse was down, the expression of the face calm, and the patient seemed quite easy. On 18th I ordered her an alkaline mixture. On 14th she was out of bed, and in a few days was running about.

Case XII.—Master M. S., aged five years, brother to previous patient, was visited by me on 26th March, 1881. He was suffering from swelling of wrist and knee-joints; pulse 120; thirst excessive; throat congested, and had not slept for two days. His mother knowing the value of the blister in the former case had thought of applying one, but before doing so consulted me. I ordered a blister, 3x8 inches, to be applied for twelve hours over the cardiac region and cotton wool over the inflamed joints.

27th March.—Patient was seen by Dr. Harkin along with me; all tenderness of the joints gone, but some puffing still remained over the wrist-joints; pulse 120. The little patient complained of headache, and the pupils were dilated; he had also on the anterior surface of his abdomen and legs a number of spots very much resembling those of purpura. Ordered him some bromide with the bicarbonate of potassium, also counter-irritation to the nape of the neck.

29th.—All pain and swelling of the joints gone; can move hands and legs freely; pulse 100; taking food; still has an inflamed throat, for which I prescribed.

3rd April.—Patient quite well, with the exception of being a little weak and anæmic.

Case XIII.—D. C., aged twenty-two, was admitted into the Royal Hospital on the 1st March, 1881, suffering from a lacerated wound of little finger of left hand, followed by an attack of diffuse cellulitis of forearm and

arm. After free incisions he became convalescent at the end of three weeks. He had been up but one day when he began to expectorate bloody mucus, and complained of sore throat.

His pharynx was found congested and œdematous; this continued for three days, when his temperature suddenly rose to 102° and pulse to 120. He also complained of pain in the left ankle-joint. Cotton wool was ordered and milk diet.

Next day left knee and elbow-joints were involved; temperature 103.4°, pulse 120. Great pain and acid perspirations were complained of. Dr. Harkin this day visited the patient by request. Upon examination of the heart a mitral whiff was detected.

Emplastrum lyttæ, 3x3 inches, was now applied over the cardiac region for ten hours. Upon its removal the patient declared himself almost free from pain, although the joints were still swollen. The temperature, which, on the application of the blister, stood at 103.4°, gradually came down to 99° in forty-eight hours. The patient made a rapid recovery, and left hospital three weeks from the commencement of the rheumatic attack.

Perhaps the most striking fact in the history of these thirteen cases is the rapidity of the cure and the uniform appearance of delitescence within a few hours after the application of the blister, varied somewhat by the difference in the ages of the patients, their constitutional peculiarities, and other circumstances. In the majority anæmia was present; in six the disease was preceded by an attack of tonsillitis; one had urticaria; another had erythema nodosum as an accompaniment. There is a sort of order observed in the disappearance of the symptoms—the pain in the joints and insomnia are the first to disappear, then swelling and redness and stiffness of the limbs, then perspiration, muddy urine, and rapid pulse, then, among the last, generally about forty-eight hours after the application of the blister, the temperature becomes normal, about the period at which hyperpyrexia yields to powerful doses of salicin.

I have also observed in a few cases an attempt at recrudescence upon the third day, which dies out in twenty-four hours. The immediate removal of the arthritic symptoms leaves us face to face with the cardiac ailments should they assume a troublesome development, to be treated in the ordinary way. It will be observed that there was not any relapse in the correct sense of the word.

In the cases of S. and G., which required my after-attention, there was not a relapse, but a reproduction of the disease by a similar cause as at first—viz., by undue exposure to cold and moisture after almost complete convalescence. According to Latham, “perfect cure does not contemplate that after their removal diseases shall never return; but it does contemplate that before they can begin to return, their actuating cause will have to

begin also.”¹

Having, then, given in detail a record of facts and phenomena, as observed by myself and professional friends, exhibited in thirteen consecutive cases of acute and subacute rheumatism, the question arises—Were these unprecedented results due to fortuitous circumstances, to accidental combinations, or to peculiar constitutional conditions of the respective patients? Or does the unvarying effect of this simple remedy indicate the existence of a hitherto unknown law that dominates and controls the manifestation, course, and termination of this disease? I cannot doubt that an invariable sequence of phenomena must have a common cause, that in the case of acute rheumatism those phenomena spring up from a seminal principle to which all our efforts should be directed; and if it be true that scientific therapeutics often elucidate the nature of disease, then the unailing effect of this simple remedy goes far to prove that the fons et origo of this malady is to be found in the heart itself.

Cullen, in the preface to his “Nosology,” page 16, says—“Remedies cure diseases only in so far as they remove their proximate causes.” If, then, Cullen’s dictum be accepted, and if a blister over the region of the heart cures the disease, and even its articular complications, it surely would not be unsafe to infer that the proximate cause itself is located in the same region—the heart.

According to Dr. Peter Latham, “the treatment of diseases is, in fact, a part of their pathology. What they need and what they can bear, the kind and strength of the remedy, and the changes which follow its application, are among the surest tests of their nature and tendency.”²

I regard acute rheumatism as essentially a cardiac disease, as a specific form of endocarditis, generally allied with myocarditis, which, if not recognised and treated at its onset, speedily modifies the composition of the blood, the innervation and calorification of the body. In its ordinary course it soon gives rise to lesions in the textures, frequently in the pericardium, the pleura, the lungs, muscles, membranes of the brain, the neurilemma, and, in fact, in any organ accessible to arterial and nervous influence. I believe with Cullen, although in a wider sense, that its cause is external and in general known, in opposition to the believers in the humoral pathology, who attribute its origin to a materies morbi, or ζύμη in the blood. I look upon rheumatic fever as an inflammatory disease of local origin, and I agree with Dr. Pollock, “that the tendency of modern thought is to believe less in constitutional and more in local disorders, and to trace every systemic disturbance to some tangible part of the body.”³

The clinical history of endocarditis is both interesting

and instructive. In the early part of this century many English physicians had recognised the intimate relation that subsisted between acute rheumatism and cardiac disease. Dr. Peter Latham was the first to discover the coexistence of abnormal murmur in every case of heart disease arising in rheumatism, but did not recognise its special meaning. Drs. Stokes and Watson further advanced our knowledge by separating the bellows from the friction sound, and by determining the relative value and meaning of each. In 1840, Bouillaud proved by post mortem examination that all those dying with bellows sound died of endocarditis, and he regarded the so-called cardiac complications as the [?] features of the disease; he taught that one-half, other authorities taught that one-third, of the sufferers from acute rheumatism were also affected with endocarditis; but these calculations do not affect the question, as many observers, mistaking the product of inflammation for the symptoms, only recognise those as true cases of endocarditis in which they can detect by the ear the changes worked in the valves and lining membrane of the heart by acute disease. More accurate observers recognise the advent of cardiac inflammation by signs which often precede the endocardial murmur, such as tumultuous action of the heart, a certain length and roughness of the sounds, and other pathognomonic symptoms. Further, Pfeuffer and Hueter, quoted by Senator,¹ look upon cardiac disease as the primary change and the articular disorder as the consequence, the latter stating that “endocarditis may be present without giving rise to either subjective or objective symptoms;” he also suggests “that it may very well precede the inflammation of the joints, even although not recognised till afterwards,” and says “that its presence must be assumed in those cases which appear to run their course without any cardiac complication.” Dr. Stokes, in his work on “Diseases of the Heart and Aorta,” states, “that cardiac inflammation may be developed unattended by any evidence of valvular lesion, and that he has seen cases that could not be explained on any hypothesis except that of the absence of murmur in endocarditis” (page 103). We may then fairly conclude that while the presence of endocardial murmur, along with the other physical signs, will satisfy the most sceptical, its absence does not negative the existence of organic disease. This also explains the difficulty started by Aitken (Vol. I., p. 814), “why the rheumatic inflammation of the joints is frequently preceded by febrile disturbance, and also why sometimes the fever runs so high before any local symptoms have established themselves.”

While, therefore, the cardiac origin of acute rheumatism commends itself strongly to our acceptance, there may be in addition what has been called an overruling neurosis, and doubtless where we have so

¹ Clinical Lectures. Vol. II., p. 417.

¹ Ziemssen’s Cyclopædia. Vol. XXI., p. 22.

much pain of a flitting character the nervous system must be deeply implicated, but it is difficult to determine whether the neurotic symptoms precede or follow the local phlegmasiæ. The rising school of modern neuro-pathologists, some of whom look upon gout as principally a neuropathy, might tell us that the initiative chill which ushers in the rheumatic attack sets up peripheral irritation, and that the cardiac and articular affections are the result of a disturbance of innervation. Indeed, the experience of late years, which has demonstrated the dependence of certain joint affections (arthritis deformans) upon chronic inflammatory changes in the spinal cord, might justify the idea of an irritation of nervous centres being suddenly propagated to the central origin of nerve supply to distant organs, so as by this means to stir up disease and pain. The special action of nerve influence upon joints has engaged the attention of eminent men, such as Charcot, Ball, Ord, and Buzzard.

The last writer starts the hypothesis that these neuropathic osseous lesions may depend on an invasion of a part of the medulla oblongata closely adjacent to the roots of the vagi. "Is there something," he says, "which we may call provisionally a trophic centre for the osseous and articular system in the immediate neighbourhood of the roots of the vagi? The discovery of such a centre would materially help us to explain the remarkable association of cardiac complications with the joint affections of acute rheumatism, as well as the sweating character of the disease and the occasional hyperpyrexia which occurs in it" Should the pathogeny of rheumatic fever and of gout on further inquiry be found to be identical, it may also be discovered that, owning a common origin, they may also prove to be amenable to similar cure.

As opposed to the theory of the local origin of acute rheumatism, there are two hypotheses which divide the suffrages of the profession—viz., that of a materies morbi poisoning the blood and being the cause of fibrinous deposits on the lining membrane and valves, and of the exudations into the pericardium and joints, and the other based on a chemical idea that the dyscrasis is owing to the presence of lactic acid in the blood, supposed to be generated by some faulty metamorphosis, and although intangible, yet existing—its presence being manifested by pain, and acidity in the sweat and urine. The first of these hypotheses is supposed by such authorities as Holland and Fuller to be demonstrated by the alteration in the composition of the blood, the increase of fibrin, the constancy of premonitory fever, and the frequent occurrence of metastasis—the heart and great vessels being in their view the passive depositories of fibrinous growths. Basham, Garrod, and Fuller incline to the opinion that some morbid matter is generated within the blood, or is not eliminated, and it was with the intent of destroying this virus that the eliminating treatment of Drs. Dechelly and Davies was

introduced. It is remarkable, however, that according to Senator the plan failed to render the urine alkaline, and that if any poison were thereby removed from the system it was not an acid, as the serum produced by vesication was invariably alkaline. This observation replies by anticipation to the assertion that the disease has its origin in an acid state of the blood, as advanced by Dr. Prout. With the intention, then, of destroying the lactic acid assumed to be present many practitioners prescribe alkalies in large quantities. If relief is experienced the argument takes this shape, that as alkalies are in their nature antacid, there must have existed in the circulation of the patient a sensible amount of acid. The fact too of the urine becoming alkaline sometimes during their use gives further countenance to the assumption. The admitted fact, however, that neither uric nor lactic acid has ever yet been discovered in the blood of the rheumatic patient, though plentiful in that of the gouty, should settle this question in the negative.

The lactic acid hypothesis has been recalled to revived consideration by a paper published in *The British Medical Journal* by Balthazar Foster, in December, 1871. Under the heading of "The Synthesis of Acute Rheumatism," he publishes two cases bearing upon the point, and expresses the opinion that "these facts will strengthen the evidence which points to lactic acid as the poison of rheumatic fever." The observations arose incidentally from an inquiry into the effects of certain drugs (among the rest lactic acid) on the sugar excretion in diabetes. It is not my intention to question the correctness of the facts adduced by so accurate an observer. The results are quite consonant with the recognised effects of lactic acid. I must, however, take exception to the conclusions deduced from them, and beg to offer a solution more in accordance with the true clinical significance of the published signs and symptoms.

In the first case, Wright, suffering from diabetes, who had never suffered from rheumatism, is fed on a strictly animal diet, nitrogenous—a diet which in healthy persons predisposes to a certain blood disease, not rheumatic however. Consequent upon the internal administration of the lactic acid, he had six attacks of articular pains fairly attributable to that agent; but, when we come from synthesis to analysis we find that when in place of describing "acute pains in the joints and flying pains about his limbs," as the result of the dose, B. Foster particularises the joints affected.

He says—"The small joints of the fingers of both hands, the wrists, and in a less degree the elbows had become red, swollen, and painful. Moderate perspiration and heart clear. Second attack.—Metacarpo-phalangeal and first phalangeal articulations of the first and second fingers of each hand were red, hot, swollen, and painful. Less pain in the knuckles in the evening. On the evening of April 5th and 6th, after taking the medicine, the pains returned to the knuckles and left

wrist. April 13th—Right wrist. June—Two attacks in hand and wrists. July 8th—Wrists and elbows. July 11th—Right and left wrist and knuckles of right hand; left knee red and swollen.”

In the second case only one attack occurred, and the evidence derived from this case is little worth, since the only joint swollen was the right knee, which was faintly red. How unlike an attack of acute rheumatism, in which we look for a rigor, swelling and pain in the large articulations, excessive sweating, muddy urine, and heart affections. Does it not closely realise our conception of gout, which selects the smaller joints, the fingers, wrists, and knuckles, for its habitat, and what more efficient way could we propose to induce an attack of gout than by introducing into the system lactic acid, generally recognised as the potent factor of the disease, and always present in the blood of the gouty patient? We cannot in this inquiry overlook the fact of the intimate connexion that exists between gout and glycosuria. Garrod states that gout and diabetes occasionally occur in the same individual, and Dr. Dyce Duckworth, in a very suggestive paper which appeared in *The British Medical Journal*, March 26th, 1881, refers to the remarkable relation which exists between gout and glycosuria. “Diabetes mellitus,” he says, “is met with in certain members of gouty families, some having gout alternating with glycosuria, the glucose alternates with uric acid.” Thus it would appear that Dr. Foster’s cases are instances of glycosuria and gout appearing in the same individuals, and one can understand how lactic acid, whether pure or altered in its passage to the blood, would react upon the sugar or glucose in the system, and speedily change the saccharine to the acetous fermentation. Had Foster thought of testing the nature of the disease by a blister, the absence or the presence of lactic acid in the serum effused would have aided in the diagnosis.

But more cogent, in my mind, than critical commentary, more conclusive than any inductive or deductive process of reasoning, more fatal to the hypothesis that acute rheumatism is a disease of zymotic or of constitutional origin, is the fact I have demonstrated that it may be speedily and effectually cured by a topical external remedy, by one which could not possibly modify a diseased condition of the blood or neutralise an acid poison permeating the system.

In presenting these cases and this novel plan of cure, knowing how prone human nature is to self-deception, I have carefully guarded against the personal element by inviting the presence and co-operation of medical men of ability and scientific acquirements and independent judgment. I shall conclude this paper by expressing the hope that this simple plan will commend itself to the consideration of the profession at large, as, while aiming at a truer and simpler pathology, at one fell stroke it puts an end to the pains and perils of polyarthritis, and saves the helpless invalid

from the horrors of meddling polypharmacy.

The President Dr. J. W. Browne came in at 9.5 p.m. and took the chair, Dr. Whitla vacating.

The discussion of Dr. Harkin’s paper was postponed to the next meeting.

J. Walton Browne

Eleventh Meeting of the Society was held upon Tuesday April 26th 1881 in the Royal Hospital.

Present, Dr. J. W. Browne President, Professor Dill, Drs. Harkin, Wales snr., Speer, Dempsey, Esler, Wadsworth, Stewart, F. Wales, Whitla. Drs. McFarland and Byers were visitors introduced by the President. Several students were present.

Dr. Harkin then gave a short resume of his paper upon acute rheumatism in which he advocated the use of a blister over the cardiac region.

The debate following was freely entered into [by] the members present.

J. Walton Browne M.D.

The Twelfth Meeting of the Society was held upon Tuesday May 17th 1881.

Present, Dr. J. W. Browne President, Professor Gordon, Drs. O’Neill, Whitla and Workman and Wadsworth, Esler.

Dr. Gordon read a paper and exhibited some beautiful and interesting specimens of extra-capsular fracture of neck of femur.¹

Paper (cont.):² Second Form.—In the form which I have described as the first, the line of fracture in front may be through the anterior intertrochanteric line, or it may include a large portion of the anterior surface of the upper part of the shaft extending almost to its outer surface. Now in this, the second form, the line of fracture in front is along the inner margin of the anterior intertrochanteric line; above and behind it is at the point of reflection of the compact tissue of the base of the neck, where it changes its direction to form the apex of the trochanter and the posterior intertrochanteric line, above or below the lesser trochanter. Its course is, therefore, more limited to the base of the neck than the first form. From the direction of the force which is applied to the fore and upper part of the head, the base of the neck in front penetrates behind the compact tissue forming the upper part of the shaft; and, as the line of fracture behind is at the junction of the base of the neck with the posterior intertrochanteric line, it follows that the entire base of the neck penetrates the trochanter, and, in consequence of this mode of penetration, the trochanteric fragment is much greater than in any of the other forms. I have applied to this the term penetration en masse. In many instances nearly the

¹ [Part two of a two-part lecture. Part one was given on 8 March 1881 (see page 1413).]

² [*Dublin Journal of Medical Science*, 1881, v72, p3.]

whole of the trochanter is separated from the shaft above. Behind it extends almost, in some instances, to the outer surface of the shaft and below, including the lesser trochanter and part of the shaft below and behind it all in one fragment. In one of the specimens before me at present the depth of the trochanteric fragment is four inches, and its breadth two inches. The angle formed between the neck and the shaft varies but little; it is often a right angle, or sometimes more or even less than a right angle. As the base of the neck is directed more or less backward, there is very little eversion of the limb. Sometimes there is well-marked inversion, and occasionally neither eversion nor inversion. Owing to the depth to which the base has penetrated, there is well-marked shortening of the limb, and a manual examination of the upper end of the shaft renders the diagnosis usually very easy—the great increase in the antero-posterior diameter, from the flattening of the great trochanter, and the great size of the trochanteric fragment, and also often a well-marked trochanteric groove. As nearly the whole of the apex of the trochanter is broken off and carried backwards, measurement of the outer surface of the femur shows a shortening in many instances equal to the depth of the trochanter, or more than an inch. Passing the finger along the outer bifurcation of the *linea aspera* detects at once the prominence of the fragment, contrasting remarkably with the opposite femur. If there is not much swelling, and the limb slightly everted, we may be able to feel the prominence of the anterior intertrochanteric line, which in recent cases would be very painful on pressure. I think that in this case the moment the fracture occurs, instead of the pelvis gravitating backwards as in the first form, it falls forwards; or, in other words, the patient will be found immediately after the accident lying on his back, with the toes remarkably turned out, in the first form, while in this, the second form, the patient will be found prone, with the limb scarcely at all everted or inverted. It is this form which some authors have described as non-impacted extra-capsular fracture—that is to say, where the base of the neck rests upon the large flattened trochanteric fragment and the upper end of the shaft, where penetration has been carried to such an extent that impaction no longer exists.

I have several specimens of the extra-capsular non-impacted fracture. They all occurred in persons of extreme old age, in which there was great fragility of the bone, from senile atrophy, and the force which caused the accident was not of extreme violence, but was by simply falling and alighting on the trochanter.

Treatment.—The treatment of this form is the same as that of the first. Indeed, when I compare two well-marked specimens, I find, in the first form, if the force had been continued it would have placed the base of the neck upon the front of the shaft, with the trochanteric fragment attached to the shaft, whereas, in the second form, the base of the neck would have gone behind the

shaft, with the neck attached to the trochanteric fragment. As regards the impaction of bone, I may here remark that I have never seen any bone whatever, no matter how deeply the fragments were driven into each other, held firmly together. If I take an axe and drive it into a piece of wood, the resiliency of the wood will hold it firmly impacted, but in bone it is the fibrous tissue and not the osseous tissue that holds the fragments firmly together, for if we remove the fibrous tissue the osseous fragments will drop apart from each other.

Third Form.—The basis upon which I found the third form is the deep penetration of the trochanter above and behind, the result of which is a great increase of the angle between the shaft and the neck.

I have only two specimens of this form, and the propriety of considering them as a third form might be questioned, as the mode of penetration above is not exactly the same in each. In one the penetration is deeper above and behind, breaking off a comparatively small part of the upper and posterior part of the trochanter. The increase of the angle is very decided, and the shortening was so slight that it could not be detected by measurement. In other respects it resembles the first form in which the head is carried backwards, the base of the neck forming a salient angle in front.

Diagnosis.—The diagnosis could have been easily made out by the prominence of the base of the neck in front, the increase of the antero-posterior diameter being confined to the apex of the trochanter, without shortening of the limb. In the second specimen the base of the neck has penetrated deeply above, fissuring the trochanter, whilst below it is started forwards, slightly overlapping the shaft in front of the lesser trochanter. The angle is very obtuse. A similar specimen is figured by Mr. (afterwards Sir) Charles Bell in his work on "Fractures of the Thigh Bone."

Fourth Form.—In the fourth form, as in some specimens of the other three varieties, the fracture follows the base of the neck as described by anatomists. The penetration, although slight, is most marked between the lesser trochanter and the anterior internal ridge of the shaft. The compact tissue being thick and strong here, the base of the neck entering as a wedge splits the shaft. In one instance the fracture passes downwards to four inches below the base of the trochanter, in the other it is eight inches in length. In one of these the trochanter is simply fissured above. The patient from whom this specimen was obtained was under my own care in hospital. On making my usual visit I inquired from the house-surgeon the nature of the case. He replied it was a very oblique fracture of the upper third of the femur. On the fourth day afterwards the patient was attacked with traumatic delirium, and as he had displaced the long splint which had been applied, I saw and felt on the outer surface of the thigh four inches below the lesser trochanter the lower end of the upper fragment sharp, thin, and prominent. There was no

shortening or eversion of the limb.

He died on the seventh day. The femur was removed after death, and when given to me by the house-surgeon I thought it was a very oblique fracture proceeding from the base of the neck below, running down across the rough ridge from the attachment of the gluteus maximus. After that it coursed round the outer surface of the femur, and ran up to the capsule at the middle of the base of the neck. On removing the capsule and soft textures I found that the base of the neck moved upon the trochanter, and that this really oblique fracture was caused by the base of the neck penetrating the shaft opposite the lesser trochanter. Had this patient escaped traumatic delirium, there would have been no evidence whatever that he had sustained an extra-capsular fracture. There would have been no eversion, inversion, or shortening of the limb; there would have been no fracture of the trochanter capable of detection. The attachment of the gluteus maximus behind to the linea aspera prevented shortening. In front the upper end of the shaft was firmly attached to and fixed by the capsule. In no part was the penetration greater than half a line.

The second specimen was presented to me by a former pupil of mine, Dr. Chambers. In it the portion of the shaft attached to the trochanter is eight inches in length. It was even sharper and thinner than the first specimen. The amount of penetration of the base of the neck, however, was much greater, but in neither of the two instances was the trochanter broken in the usual way in these fractures. Indeed, in both specimens it may be said to consist of head and neck one fragment, the greater and lesser trochanter to the upper and outer surface of the shaft form the second fragment, whilst the remainder of the shaft forms the third fragment.

Now, this form is exceptional in several respects:— (1) The trochanter will be felt to be normal. (2) There will be no shortening, (3) inversion, (4) or eversion. The obliquity and thinness of the fragment, which is split from the upper and outer part of the shaft of the femur, would be sufficiently diagnostic, and I could hardly conceive any other force excepting the base of the neck forming such an oblique and thin fragment. (5) It is also exceptional in its treatment, as it would require the use of the long splint to hold the split fragments together.

Fifth Form.—In the fifth form the fracture of the base is the usual one, but it acts on the neck by running obliquely upwards towards the head, splitting the neck into two unequal parts. The diameter of the neck being thus diminished, that portion of the neck attached to the head penetrates deeply, and reaches in the two specimens which I have to the inner surface of the upper end of the shaft. Indeed, I have several specimens in which large portions of the neck have been broken off and have disappeared, leaving merely the portion of the neck which was attached to the head. The trochanter is

also fissured, but not widened so much as to enable us to detect any lesion of it.

Diagnosis.—In the diagnosis the signs would be regarded as indicating an intra- rather than an extra-capsular fracture.

J. Walton Browne

Thirteenth Meeting of the Society was held upon Tuesday June 28th 1881 in the Belfast Royal Hospital.

Present, Dr. J. W. Browne in the chair, Professor Dill, Drs. Aickin, Fagan, Esler, Smith jnr., and Whitla and Dr. Wales snr.

Dr. Whitla proposed Dr. W. MacCormac and Dr. J. W. Moore, the former of London, the latter of Dublin, as honorary members of the Society to be balloted for next annual meeting.

Dr. J. W. Browne, Professor Dill and Mr. Fagan seconded the nomination of each candidate.

Dr. McKeown whose name was on the paper could not attend.

Dr. Fagan read an interesting paper upon the treatment of hernia.

Dr. J. W. Browne the President exhibited a child upon whom he operated for cicatrix.

J. Walton Browne M.D. President

Annual Meeting Session 1880–1881 July 5th 1881.

Present, J. W. Browne President in the chair, Professor Dill Ex-President, Drs. Harkin, Wheeler, Wales, O'Malley, Dempsey, O'Neill, Kevin, Smith (house surgeon), Speer, Wadsworth, Graham.

The Honorary Secretary read the report of Council which was adopted.

COUNCIL REPORT

The Council reported "that the Session which has just terminated has been upon the whole most satisfactory. The large number of thirteen meetings took place, and were well attended. This number is in excess of that of the past ten years (with one exception); but the matter which the Council feel most reason to congratulate themselves upon is the nature of the papers submitted during the past Session. About twenty were read at the different meetings, and they mention especially the two able and original monographs of Professor Gordon on Extra-Capsular Fracture of the Neck of the Femur, and one on Intra-Capsular, which may be said to have thrown entirely new light on this hitherto obscure part of the field of surgery. Three very learned papers were read by Dr. Anderson on the Embryology, Homology, and Morphology of the Tongue Muscles, and an original and exhaustive paper by Dr. Harkin on Acute Rheumatism.

The Session will be memorable from the attempt made by the Society to lead to reform in some of the medical charity abuses of Belfast A Committee was

Ulster Medical Society
Session 1880-1881
President John Walton Browne

appointed (after the question had been ably introduced by Dr. Esler) to report upon the matter, and the following were the members of committee : Drs. Browne, Harkin, Fagan, Esler, Jn. Moore, McKeown, Wadsworth, Core, and Whitla, and they drew up a clear and practical report, which has been already placed in the hands of the members.

Many interesting specimens were laid before the Society, and several patients exhibited.

Seven new members were added to the ranks, and we have again the happy memory of being without an obituary column. The transactions of the previous Session have been printed and circulated in a handsome volume of 130 pages, which forms a record of the work done by the Society, and which contrasts favourably with that of past years.

The Treasurer reported a balance in hand of £57 10a 7d. His report was adopted.

Present, Dr. Harkin in the chair, Dr. J. W. Browne, John Moore, Dempsey, Mackenzie, Smith (Royal Hospital), and the Secretary.

Proposed and seconded and passed unanimously that the recommendations of the Council to entertain Sir William MacCormac to the Annual Dinner upon Monday October 3rd 1881 was adopted. Time fixed 7:30 p.m.

It was agreed to have the dinner in the Imperial Hotel and the guests recommended by the Council were agreed to, and the Secretary was instructed to ask them as Society guests.

To The Ulster Medical Society in payment to the Treasurer (Dr. Esler) Co.

*Examined found correct
John Lewis
Auditor
W. J. Browne*

Professor Cuming was elected President.

Drs. Fagan and McKeown were elected Vice-Presidents;

And the following gentleman were elected members of Council: Dr. Wadsworth, Dr. Beck jnr, Dr. Clement, Dr. Johnson (David), Dr. McConnell, Dr. Dill. Drs. Whitla and Esler were unanimously elected Secretary and Treasurer.

A vote of thanks was carried to Drs. Core and Workman for their services as Librarians. Dr. Dempsey was elected Librarian. Dr. Wales, Smith (house surgeon), Core and Speer were elected Library committee. Drs. O'Neill and McKenzie were appointed auditors. Dr. Workman was appointed Pathological Secretary.

Dr. J. W. Moore, Dublin, [and] Dr. William MacCormac, London, were unanimously elected Honorary members.

James Cuming M.D.

Special Meeting Session 1880-81.

ULSTER MEDICAL SOCIETY

SESSION 1881–82

**Session 1881–1882 President Professor Cuming
The Opening Meeting of the Session was held upon
Tuesday evening 8th November 1881.**

There were present Professor Cuming President in the chair, Drs. J. W. Browne, Wales, Dill, Harkin, John Moore, Fagan, Dempsey, Esler, Smith (house surgeon Royal Hospital), Stewart, Clements, Kevin and Whitla.

Professor Cuming opened the session with an able address taking for his subject "Some changes in medical opinion and practice during the last 30 years".

On the motion of Dr. John Moore seconded by Dr. Wales the President was thanked for his eloquent address which he consented to hand over to the Society to appear in the Transactions.¹

Dr. Dill proposed and Dr. Whitla seconded a vote of thanks to Dr. Browne the late President.

Dr. Whitla proposed and Dr. Moore seconded the nomination of Dr. Thompson, Omagh, as a member of the Society.

James Cuming M.D.

Second Meeting of the Session was held upon Tuesday 22nd November 1881.

Present, Professor Cuming in the chair, Professor Dill, Drs. J. W. Browne, Wales, Fagan, D. Johnston, Smith, Jnr., Dempsey, O'Neill, Clements, Whitla.

Dr. Thompson, Omagh, was unanimously elected member of the Society.

Dr. Whitla proposed and Dr. Fagan seconded the nomination of Drs. McFarland and T. K. Wheeler, Jnr.

Dr. J. W. Browne showed several interesting specimens and Dr. O'Neill exhibited a diseased liver.

The hour being late it was decided to postpone the remaining papers on the circular till the next meeting.

James Cuming M.D., President

Third Meeting of the Society was held upon Tuesday 6th December 1881.

Present, Professor Cuming President in the chair, Dr. John Moore, J. W. Browne, Fagan, Core, Clements, Kevin, Wadsworth, Whitla, Professor Dill.

Drs. McFarland and T. K. Wheeler were elected members of the Society unanimously.

Dr. John Moore showed an interesting specimen of rare injury to the eyeball.

Dr. Whitla reported a case of strychnine poisoning in which recovery followed a dose of 6 grains.

Mr. Fagan read notes of cases of blood effusion into the knee joint.

The President proposed and the Secretary seconded the nomination of Dr. Byers.

James Moore M.D.

The Fourth Meeting was held upon January 3rd 1882.

Present, Dr. James Moore in the chair, Professor Dill, Drs. J. W. Browne, McKeown, Dempsey, Anderson, Esler, and Whitla.

Dr. McKeown showed an interesting case of tumour of the eye.

He also read an interesting paper upon pilocarpine and showed the effects of the drug in two patients to whom he administered it before the Society.

Paper:¹ *I purpose bringing before you, as shortly as possible, my experience of the use of pilocarpine; but before doing so, I shall show you its usual effects by injecting subcutaneously the two patients whom I have brought here for the purpose. The preparation I employ is a solution of the nitrate of pilocarpine, and the strength is 1 in 20. The younger of the two, a lad about twelve years of age, has been treated for about a couple of months by the injection almost daily of from four to five minims of the solution, whilst the elder, a young man of twenty years, has been treated for a similar period by the injection of five to six minims daily. You can observe now, immediately after the injection in both cases, great quickening of the heart's action and flushing of the face, followed by copious perspiration over the whole body, and free salivation. If you open the mouth, and place your finger for a few seconds on the opening of the duct of either the sub-maxillary or parotid gland, and afterwards remove it, you will find a regular spout of fluid from the duct. The laryngeal and nasal secretions are also increased to some extent, and likewise it is said the bronchial. The internal muscular apparatus of the eye is affected, a sort of spasm of accommodation being induced—hence patients complain of dimness of vision for distance. It is remarkable also that the genito-urinary organs in both male and female are affected. In these two cases, shortly after the injection there is a desire to pass water, and this, I may remark, is a very constant symptom. It does not arise from an increased flow, but rather from a contraction of the muscular coats of the bladder. The desire exists even when there is little or no urine to be voided—at the same time, often severe pain at the end of the penis is experienced. Special action seems also to be exerted on the vasomotor centre regulating the vascular supply to the penis. In both these cases erection of that organ takes place. I have been told by the elder of the two of another effect, which is rather unusual—viz., the ejection occasionally of a large quantity of pretty clear fluid (about a pint) from the stomach, although he had not taken any fluid for a long time previously, and had not swallowed any saliva. In addition I may mention that*

¹ [Not found.]

¹ [Dublin Journal of Medical Science, 1882, v73, p398.]

in two instances hiccough, continuing for hours, followed the injection. In one case each injection was followed by a bloody discharge from the female genital passages, without pain or other symptom anywhere. In another case the menstrual period was anticipated by a couple of days. Giddiness, with tendency to faintness, also sickness and vomiting, are not unusual.

Putting aside altogether the question of the exact *modus operandi* of the drug, which would lead us too much into vasomotor theories, let us look to the facts which are patent to everyone. The heart, the capillaries of the skin, the sudoriparous glands, the submaxillary and parotid glands, the accommodative apparatus of the eye, the muscular coats of the bladder, the vascular supply of the penis, the female genital organs, the stomachal secretion, the diaphragm, are all affected, some with unvarying regularity, and some occasionally.

Probable Effect on the Circulation in parts not under Observation.—Seeing now the dilatation of vessels of the cutaneous surface, it is now for you to think of what may—indeed what I might say almost certainly does—take place in other extensive vascular areas not under observation. If the whole of the capillaries of the body, with the arteries and veins, were in the same condition of dilatation as those of the cutaneous surface, it is almost a question whether the circulation could be carried on at all.

Now, physiological experiments have shown that, when, by some means or other, dilatation of a large vascular area was established, a balancing diminution of the vessels in some other large area took place simultaneously. We have good grounds for believing that pilocarpine acts in this way. We endeavour to relieve a stagnant internal vascular tract, and promote absorption of effusions by opening up the surface channels, and draining from the blood flowing therein a large quantity of fluid. This is really our object, whether we are dealing with fluid in the peritoneum or in the eye, with a congested kidney, or suppressed eruptive disease. I have remarked that giddiness and faintness are often complained of. Do these symptoms not point to a diminution of the cerebral supply of blood, and have we not an indication for the use of pilocarpine in affections of the brain and its membranes, supposed to be attended with increased vascularity and effusion?

With these general remarks I now pass more particularly to my clinical experience. You must not expect me to deal with the question before us in an exhaustive or very systematic manner, but rather in a suggestive way.

Action in a Case of Painful Menstruation.—From what you have seen of the influence of the drug on the sudoriparous secretion, you would naturally expect that it would have a salutary influence in cases in which that secretion was absent. I had an opportunity of putting this to the test, but with a very different result from what I had anticipated.

Case I.—A lady, apparently about thirty-five years of age, consulted me for an aural affection. I came to the conclusion that it was of a nervous character. She had been a victim to severe neuralgia of the head and face, for which she had consulted several London practitioners skilled in nervous diseases, but without material benefit. She suffered likewise from extremely painful menstruation, for which she had been under the care of several gynecologists, but had obtained no relief. She casually told me that she never perspired, no matter how much exercise she took—that the only effect of the exercise was great flushing and heat of the head and trunk, attended with throbbing in the head. I resolved to try pilocarpine.

I began with a subcutaneous dose of six minims of the solution. It caused great congestion of the head, the chest became also of a rosy tint, there was copious salivation, but no cutaneous secretion whatever. The feet and legs remained cold. Next day she told me her illness came on during the night, and that she had never had so little pain. I continued the pilocarpine for a week in gradually increasing doses till I reached 12 minims, equivalent to $\frac{1}{20}$ ths of a grain of the nitrate of pilocarpine, but without inducing perspiration. The feet and legs always remained cold. Injection of the drug in the leg, which I tried on one occasion, did not at all improve the circulation in the lower extremities. I tried to aid the action of pilocarpine by hot jars to the feet and friction of the legs, but without appreciable effect. The vascular area of the lower extremities was, therefore, stubborn to pilocarpine. The lady afterwards went to India and married, but I have heard nothing of her since.

Discharge of Blood from Vagina after Injection.—I have another case at present under treatment, showing the influence of pilocarpine on the female generative organs.

Case II.—A young woman, aged eighteen years, well developed, and to all appearances healthy, has been under my care for some time for a cloudiness of the vitreous in one eye, quickly appearing and disappearing, probably from some vasomotor disturbance. There is a patch of hemorrhagic effusion in the chorioid. The other eye has been almost blind for a considerable time from dense opacities in the vitreous, probably of hemorrhagic origin, and completely obscuring the fundus. After treatment by pilocarpine for some time, I learned that every injection was followed immediately by a bloody discharge from the genital passage, something like what takes place during her “illness.” This discharge was unattended by any pain anywhere.

I think these two cases show that at least sometimes pilocarpine exerts a great influence on the female generative organs, and it remains for those who have large opportunities of treating diseases of women to ascertain whether this medicine can be used with advantage in certain uterine and ovarian affections.

Action on the Bladder.—I have already mentioned the influence of pilocarpine on the bladder. I would venture to throw out a hint regarding its possible use in atony of that organ. If pilocarpine cause contraction of the bladder, of which I have no doubt, might it not be used with advantage in the cases referred to after the urine has been drawn off? You know that belladonna is the agent, above all others, for incontinence of the bladder in children. As regards the bladder, then, pilocarpine contracts and exerts a sort of irritative action: belladonna, on the contrary, diminishes muscular action and soothes.

Antagonism of Pilocarpine and Belladonna.—This leads me to another point—the very general antagonism between pilocarpine and belladonna. It is rather odd that this should be manifested in precisely the same way on the muscular tissue of two organs with functions so different as the eye and the bladder. Pilocarpine has on the eye a myotic effect, and brings about increased action of the accommodative apparatus; belladonna is a mydriatic, and paralyses the accommodation. Pilocarpine increases salivary secretion; atropine diminishes it. Pilocarpine causes perspiration; atropine prevents it. Pilocarpine diminishes vascular tension, at least in some parts; atropine increases it. They both increase the pulse rate, but from different causes, on which I do not enter here.

Atropine an Antidote for a Dangerous Dose of Pilocarpine.—You will reasonably expect, from what I have said, that atropine is the antidote—and I am glad to say an effective one—should pilocarpine exert its influence to a dangerous extent. One hundredth of a grain of atropine should save a patient from any danger from a moderate dose of pilocarpine. For this reason I look upon pilocarpine as a very safe drug if the physician only take the precaution, when administering the drug on the first occasion, to remain with the patient and observe the effects. From what I have seen I consider the physician should make this an invariable rule at any rate when he uses the drug hypodermically.

Retarding Effect of Instillation of Atropine in the Eye.—An almost infinitesimal quantity of atropine to some extent prevents the full action of pilocarpine, or retards it for a considerable time. For example, in the case of the young man before you, a drop of a solution of atropine (4 grs. to the ounce) was one day applied to each eye to aid ophthalmoscopic examination. On that and the following day the usual dose of pilocarpine fell far short of its usual effects. In the case of a man aged sixty years a drop of atropine solution had been applied three times daily for some time after cataract operation. I injected 3 minims of the solution of pilocarpine to relieve chorioidal congestion. Twenty minutes after injection little effect was observed. It had caused neither perspiration nor salivation. Afterwards, however, free perspiration and salivation, attended with sickness, took place. So you will note that a considerable

difference in different patients is observed. It is, therefore, wise to ascertain exactly the susceptibility of each individual subjected to its influence.

Use of Pilocarpine in Optic Neuritis and Intra-Cranial Disease.

Case III.—A sergeant of the army was brought to me some months since, suffering from almost total blindness, resulting from optic neuritis. He stated that about six years previously, when engaged with some comrades excavating beside the Thames, a bank of earth fell upon them. It was some time before he was extricated. He suffered much from cold and wet. He lost the power of his limbs for a couple of weeks. He had had ever since severe pain in the head. When I saw him he dreaded any sudden movement of the head, or an incautious step. To shake his head caused him much pain, which he referred to the interior of the cranium. His step was quite firm, and he had no paralysis, cramps, numbness, or any other symptoms referred to the extremities. He also complained of pain in the neck on turning his head round, or bending his neck quickly. I inferred from what he told me, and from what I saw, that there was probably some chronic inflammation of the membranes of the brain and spinal cord at some part, with, perhaps, some deposit, and that rapid derivation by pilocarpine might relieve congestion, induce absorption, and perhaps improve vision. No history of syphilis. I injected pilocarpine for some time, with the result of relieving the pains, but without improving the vision. The pains were completely removed, I believe, but, as I chance not to have taken a note at the time, I do not say so absolutely. I have reason to hope that many cases of optic neuritis will, when taken early, be amenable to treatment by pilocarpine.

Case IV.—A healthy-looking lad, now under treatment, aged fourteen years, suffered for a month before he came to me from severe pain in the head and sleepiness, with failure of the right eye. A week before his visit to me his left eye came to be affected also. When I saw him I found optic neuritis of both eyes, not of a very pronounced kind, and indicated only by slight muddiness of the disc and margins, with fulness of the veins and slight exudation along the course of some of the vessels and round the macula of each eye. With the right eye only he had quantitative perception of light; with the left he could count fingers close to the eye. After treatment for a fortnight he came to see to count fingers with each eye at six feet. After the first injection he stated that he felt better, and that his sight was decidedly improved. The case was one of such gravity that although I am an advocate for simplicity of prescriptions, and no needless overlapping of remedies, yet I thought in this case, as pilocarpine is only on its trial, I would only be consulting the interests of the patient in prescribing, in addition to the pilocarpine, remedies in common use in the disease. I prescribed iodide of potassium and mercurial inunction.

Since writing the foregoing the lad has recovered perfect vision of both eyes; the state of the fundus of each eye is satisfactory, and the pain in the head and sleepiness have been entirely removed. I may digress here to state, as the result of my observation, that in children a limited meningitis is much more common than is generally supposed. Practitioners are too much in the habit of regarding meningitis as a disease which either exists in a severe form or not at all. They expect to find the full series of symptoms laid down in books, and if these do not occur in their due order they do not recognise the disease at all. I am satisfied, however, that meningitis often exists, and is only evidenced by a single symptom—viz., pain in the head. This may pass off, leaving no effect behind. Very frequently after a time, however, the vision fails, and the ophthalmic surgeon finds clear evidence of an optic neuritis or atrophy. Now, what more reasonable to suppose than that a limited part of the membranes at the base of the brain may be congested in a passing sort of way, or that this may be followed by a limited effusion affecting some part of the optic tract or central organ of vision.

Use in Scleritis and Sclero-corneitis.—I have used it in a number of cases of scleritis and sclero-corneitis with, I think, more than average success, but as the disease is one so slow, and so variously influenced by heat and cold, season, residence, &c., I really do not feel justified in saying anything positive.

Use in Detachment of the Retina.—I come now, however, to a class of cases in which pilocarpine has, to my mind, been proven superior to everything hitherto tried, and, in fact, to be the only remedy worthy of mention at all.

I refer to detachment of the retina. I am aware of only one case during a rather extensive practice of twelve years having got well. The detachment was small and peripheral, and indeed when what I considered a detachment disappeared, I began almost to doubt the correctness of my diagnosis. In only one case have I seen notable improvement by operation. In that case I removed a circular piece out of the sclerotic; and the patient, who, before operation, only discerned light from darkness, afterwards acquired so much vision that he could go about well in the daytime. For some time I have given up operation altogether, the hits were so few, and the misses so numerous. The experience of ophthalmic surgeons everywhere was just like my own. Medicines were practically useless. This was then a fair class of disease on which to try a new remedy. My attention was first directed to the subject by a paper, by Dr. Danioux, in the Paris Journal d'Ophthalmologie. The results reported by that gentleman seemed so opposed to all previous experience, and altogether so roseate, that I was rather sceptical. However, I tried the remedy, and I am glad to state that a fair proportion of the cases are greatly benefited. Many have improved far more than I could have reasonably anticipated.

Case V.—The lad before you has detachment. His case is rather anomalous. When I saw him first the tension of the left eye was quite glaucomatous. The glaucomatous process had apparently gone on for a long time. For three months, at least, he had had severe pain in and all round the eye, at times so bad as to cause fits. There was no anterior chamber, the lens apparently being quite in contact with the cornea, no iris whatever apparent at the upper part of the cornea, and only a narrow semilunar ring at the lower half of the circumference. I thought the disappearance of the iris was owing partly to atrophy and partly to its being hidden by the pushing forward of the lens. The vitreous was so cloudy that I could not make out by the ophthalmoscope anything of the state of the fundus. The sclerotic was distended and bluish in the ciliary region, with two little round projections below. He had correct perception of direction of light thrown on the eye from a mirror in various directions; could count fingers at six inches. He stated that his vision within the last few days had been better. I questioned the propriety of attempting a sclerotomy or iridectomy. Either could only be done with difficulty, and very imperfectly. I admitted him to hospital. I was surprised to find, a few days after admission, that the tension of the eye had diminished to about the normal, coincidentally with an increase in the size of the sclerotic projections. At the same time the media of the eye had cleared, and I detected easily a detachment of the retina affecting the whole of the lower half of that membrane, and hiding the disc. I could trace the upper retinal vessels close to their entrance in the disc. The sight had cleared somewhat; the detached retina was sensitive. I began to treat him with pilocarpine. There has been continuous improvement. The extent of the detachment has diminished so far that it is now of a narrow triangular form, with apex just at the disc. The disc can be easily seen. He counts fingers at ten feet.

Case VI.—This young man before you has suffered from detachment of the retina of the right eye for five years, and of the left for one year. When I saw him first I found the sensibility of the retina of each eye still well preserved. With right eye he could not count fingers; with left eye he counted fingers at one foot. He has been treated as I have told you, and now he can count fingers with the right eye at two feet, and with the left at ten feet. He can read also $8\frac{1}{2}$ Sn. at six inches. The result, considering the long continuance of the detachment, was quite unexpected. He purposes now working as a carter.

I shall only mention another case of detachment:—

Case VII.—A printer, upwards of sixty years old, always shortsighted, lost sight of right eye in the course of a day. He was a delicate-looking man, and much worn by domestic troubles of various kinds. Detachment of retina below, extending to disc. Began treatment with $\frac{3}{20}$ ths of a grain, but found this produced

giddiness, faintness, and sickness, copious perspiration, and salivation; subsequently injected only $\frac{2}{20}$ ths, and that only occasionally. After the lapse of about two weeks' treatment there was scarcely a trace of detachment, and he could read the smallest type by gaslight. He was then about to return home, but I prevailed on him to remain for further treatment, to make the result more secure. Domestic cares, however, utterly upset his head and health. He was the most despondent man I ever met. The disease relapsed to some extent, and I was obliged to discontinue treatment and send him home.

But, you may ask, are the results obtained in this disease likely to be permanent? I answer, I am not in a position to reply; time alone will test the improvement. At the same time I may remark that it is not improbable that the change in tonicity of the vessels and in the absorptive capacity brought about by this drug, and maintained for a length of time by its steady use, may remain even after the suspension of treatment. I shall, however, report after more extended experience.

Improvement of Function of Skin.—Some writers have noted great improvement in the nutrition of the hair; sometimes even a change of colour has been brought about. I have been treating a young lady for sclero-corneitis of a severe kind. She was troubled with coldness of the extremities and a general feeling of chilliness. She stated that her skin and hair were always dry, and that she never perspired. In this case I have used 5 or 6 minims daily for about three weeks. The drug produced all its usual effects—the chilliness and coldness of the feet have been relieved, her hair is no longer dry, her skin has become moist, and her complexion much improved.

Effect in Tonsillitis.—I have used pilocarpine in a number of cases of severe tonsillitis with results most satisfactory. In the first case the acute disease was of three or four days' duration, grafted on a chronic affection, and the right tonsil so much swollen that I really thought nothing would arrest the suppurative process. A single dose of $\frac{6}{20}$ ths of a grain of pilocarpine completely cut short the disease. Afterwards, with the view of watching its effects in these cases, I admitted such as chanced to come before me (three altogether) as intern patients. They all seemed to me such as would go on to suppuration. The relief was immediate in every instance. I have found that patients who on admission were not able to swallow at all could do so very well shortly after a single injection. I have only had to keep the patients in hospital from one to three days. I cannot too strongly recommend you all to adopt this treatment.

Dose.—Some of you, from what you have read in the journals, may be disposed to think you may use this drug rather freely. Even one grain seems to be regarded by some as not an extra-ordinary dose, and perhaps it may not be in special diseased conditions. For example, in cases of suppressed eruptive diseases, or in case of

great vascular tension, it may be safe to give considerable doses; but, from what I have observed, I advise you strongly to feel your way. I have told you of a case in which $\frac{2}{20}$ ths of a grain in a man of sixty years old produced full effects, and $\frac{1}{20}$ th of a grain more, excessive effect. Young persons of ten years old bear a larger dose often than old persons. For persons in the prime of life you will usually find $\frac{6}{20}$ ths of a grain do all you require. Twelve-twentieths of a grain is the highest dose I have ever administered.

Mode of Administering.—When you wish a decided effect by far the better plan is to use a salt of pilocarpine, and inject it subcutaneously. In two or three minutes the full effect is developed; besides you should remember that half the virtue, perhaps, lies in its instantaneous action. The same dose administered by the mouth will usually not produce diaphoresis, and only acts slowly. You require to give a larger dose. I prefer the salt to the infusion of the leaves, because you can gauge the effects with almost mathematical accuracy.

Lacuna in our knowledge.—We must all regret that in this country there is practically an end of all research into the physiological action of drugs by experiment on animals. We may conjecture that this drug causes contraction of the cerebral vessels, but surely it would be more satisfactory and give a more sure basis for practice if we were assured definitely what effect it had on the brain exposed to view.

What I have said to you raises also the questions: What is its action on the uterus and ovaries? What are its effects on the liver, spleen, and intestinal canal? I do not see how therapeutics is to be elevated into a science without careful experimental research. It used to be that the medical profession was satisfied with extraordinary combinations of drugs, hoping that some one of the many would hit the right nail on the head. Now we require precision.

We look for active principles, and employ them in the expectation of observing definite actions on particular organs or particular nervous or vascular tracts, but how we are to employ with safety the numerous new and powerful agents which are daily brought to the notice of the profession, without some knowledge of their precise action on the lower animals, I fail to comprehend. We can only now endeavour to enlighten the Legislature, and hope for a compliance at no distant date with the reasonable requirements of the profession.

Dr. J. W. Browne showed some cases of osseous tumour.

Dr. J. W. Byers was elected member of the Society.

Fifth Meeting Session 1881–1882. President Professor Cuming M.D. January 17th 1882.

Present, Professor Cuming, J. W. Browne, John Moore,

Fagan, Anderson, Workman, Smith, Jr., Dempsey, McFarland, Whitla.

Dr. Anderson read a paper upon secondary contraction of muscle.

He also read a paper on "Some anatomical notes".

Dr. John Moore moved that a note of condolence be forwarded to the family of the late Dr. Charles Purdon.

Dr. Browne seconded the motion and it was resolved that Dr. John Moore make a draft of a letter and forward it to the secretary.

Sixth Meeting Session 1881–82. January 31st.

Present, the President Dr. Cuming in the chair, also Drs. Kevin, Byers, Esler, Graham, Samuel Browne, Jr., Dempsey, Workman, Dill.

Dr. Esler read his paper on "Whiskey".

Paper:¹ *THE word whisky is a derivation from the Irish Usquebach, the Gaelic Uisage being water, and Featha life. So that literally the word means water of life—Aqua Vitæ. Whisky of late years has become such an important article of manufacture, commerce, and export, so popular as a beverage, and so common as a medicine, that we hope a short paper on the article in its various phases will not be inappropriate to bring before a learned, a scientific, and a practical Society like the Ulster Medical. Our first inquiry shall be—"What is whisky?" The definition given in the dictionary is that "it is a spirit obtained by distillation from barley, wheat, rye, maize, or oats." But we must inquire more minutely into the process by which it is obtained, and this brings before us the subject of distillation. There are two kinds of stills—"the pot still" and the "patent." The patent still produces what is known as silent spirit, so called from being silent as to its origin. You cannot tell from what it is obtained—it is simply alcohol and water without any flavouring matter to give it a distinctive character. This is all left behind, and the alcohol so made may come from grain, potatoes, molasses, or any vegetable matter which will ferment. The spirit so obtained does not undergo as much change with age as pot-still whisky, yet it does improve as you will readily perceive from the samples I am enabled to place before you through the kindness of our local distillers, and also some of our principal merchants. You can here compare whisky only a few days old with other samples of several years of age, and you can thus judge for yourselves of the improvement by age alone. And while referring to the samples on the table I may say that I have here some of the principal whiskies advertised in the London Market—Dunville's (both patent and old still), James Wilson & Son's Bann Whisky, Kinahan's LL., and John Jameson & Son's. These are all labelled and correctly marked as to strength. I have also placed in contrast with these some of the*

stuff bought at public-houses in different parts of the town; and the only comment I can make, after a very careful examination and comparison, is that there is whisky and whiskey. Old still whisky is a spirit distilled from malt, barley, or oats, or a mixture of them, in a pot still, which brings over, together with the spirit, a variety of flavouring and other ingredients from the grain. Its distinctive character is due to the grain products, which are the sources of its flavour, and which, when sufficiently matured by keeping, undergo development into a number of volatile ethers. These ethers are the distinctive characters of good whisky—they are so subtle as to almost elude chemical analysis, but are easily discoverable by the nose and palate, and by their power to produce exhilaration. These ethers are altogether independent of the alcohol which holds them in solution. It is the presence of these ethers which distinguishes old whisky from new. New whisky, from whatever grain extracted, and even when manufactured with the greatest skill and care, contains a proportion of vegetable acids and a crude oil known as fusel oil, which renders it quite unfit for human consumption. The quantity and quality of these products depends largely on the quality of the grain used—good grain producing good whisky, just as good grapes produce good wine, and good hops good beer.

New whisky and new wine are much alike in this—that both improve with age, and neither is fit for use when new. The principal change that silent spirit undergoes by keeping is to lose strength by evaporation; it has no vegetable acid or volatile oil to be acted upon—hence, in its new state, it is most valuable on account of its greater strength; but in the case of pot-still alcohol, which holds these subtle bodies to which we have referred in solution, while the alcohol also diminishes in strength, it acts upon these oils and acids and splits them up into that which gives old spirits value as a medicine, and even as a beverage. It is said that this capacity for improvement is infinite, and that the longer good whisky is kept the better will be its bouquet. When first distilled it is reduced to an uniform strength of twenty-five per cent, over proof before it is filled into casks, because at a greater strength it changes very slowly. And here we might compare its relative strength with that of other stimulants. I quote from Dr. Whitla's recent work on Therapeutics:—"Brandy, whisky, gin, and rum contain 50 to 54 per cent, of alcohol by measure; port wine, 16; sherry, 15; claret, porter, and ale, 5 to 6 per cent."

But the point I want to draw attention to is not so much the quantity of alcohol present as the quality of the stimulant, and the ethereal and exhilarating principle as it has been matured by age. And one has only to think of the wonderful subtlety of the spirit, as seen in ether and chloroform, when alcohol is acted upon by other substances in the laboratory of the chemist, or the powerful soporific effects of chloral hydrate, which is

¹ [Dublin Journal of Medical Science, 1882, v73, p257.]

alcohol treated with chlorine, to understand something of the latent power which our national beverage possesses; and just as the acidity and harshness of unripe fruit are converted into sweetness and flavour during the natural process of ripening, so, I imagine, it is that age imparts mellowness and flavour to distilled grains, by the action of the alcohol on the crude material, which are very much like unripe fruit.

Whisky, in order to be good, must be made from good grain, distilled in a pot still, and then kept for a number of years in casks, and all this means expense, and the older the more expensive; hence it is, rather than wait for whisky to make itself by the natural process of change with age, the manufacture of whisky by the process known as “blending” has become so common. On this subject there is a mass of information given on the authority of certain Dublin distillers, of which the following are the assertions:—

Good whisky and bad are mixed together in order to make a compound acceptable to the taste of the consumer. This is the ostensible object, while really it is to produce a cheap and profitable article. It must be remembered that silent spirit has no distinctive character, is simply alcohol and water, and what serves to differentiate the other alcohols is their source. Spirit, distilled from grape mash is brandy, and has a distinctive character of its own. Spirit distilled from a malt or grain mash is whisky, and has also distinctive characters. Spirit distilled from cane sugar is rum, and could not be mistaken for anything else. But brandy, whisky, and rum may be manufactured from silent spirit.

Irish whisky has of late years become a popular beverage with the English people, and has been much esteemed and recommended by medical men in that country, and this, no doubt, on account of its being really whisky, and from the excellence of the article produced by some of the best distillers; but I have been furnished with the particulars of blends which, I fear, would not add to the reputation of the national drink.

Thus, 3,500 gallons of new provincial whisky were diluted with 2,400 gallons of silent spirit, and to this were added 786 gallons, or thirteen per cent. real Dublin whisky as a finishing touch; and this “blend” was supposed to make the whole bulk good wholesome drink—perhaps it did.

So great is the demand for Irish whisky that a large proportion of our exports are said to have been first brought across the channel to be here blended, in order to be sent abroad with an Irish permit. It is alleged that in one year upwards of 3,000,000 gallons of British spirits were so treated in Belfast alone.

The Dublin distillers say that genuine old still whisky does not require blending, and that the only thing necessary to render it fit for use is to store it up in sherry casks, which gives it a certain colour and vinous flavour, which is much esteemed. The Belfast merchants, on the other hand, maintain that it is

improved by blending, that by a judicious mixture of alcohols you get both smoothness and flavour; and some of it is put twice into sherry casks for this purpose.

In these samples the prices range from 2s. 3d. to 6s. 6d. per gallon in bond; and I believe this difference is not greater than that of the effects produced by their use, which we will investigate presently. On analysis the patent is as good as the pot still, and the new as good as the old. A practical question for the medical man or his patient will be—How and where to obtain really good whisky. Well, you must depend altogether on the dealer for quality; but by going to well-established merchants, and paying a fairly remunerative price, alcohol may be obtained which can be relied upon when prescribed to produce its characteristic therapeutic effects.

I think I have now said enough on the first part of this question, and in coming to deal with the second—what whisky does—I know I am approaching a very wide and difficult subject, and one on which opinions are very diversified.

It is a very curious fact that in nearly all the literature bearing on the action of alcohol, the evils, social and physical, are fully related and set down in the blackest colours imaginable, with scarcely a line or even a reference to its usefulness, or to the good results arising from it. And yet, in the face of all this, the nations of Europe, America, and the Colonies go on drinking it to an enormous extent, and in an increasing degree, disregarding all warnings, believing or acting as if they believed that the use of this thing does them good, and professing to feel the better for taking it.

It is easy to make out a list of charges against this active and popular agent. Our temperance friends charge it with such things as the following:—That it employs a capital in Britain alone of one hundred and seventeen millions of money; that the duties paid on it for a single year are more than thirty millions sterling; that it destroys thousands of lives; that by it multitudes are driven into workhouses, gaols, and lunatic asylums, besides being the direct maker of thousands of widows and tens of thousands of orphans.

Regarding its physical effects, one has only to look into Dr. Richardson’s lectures on alcohol to stand aghast at the frightful havoc it makes on the human frame. A simple enumeration of the diseases attributed to it is as much as we can venture to quote at present—as, for instance, “alcoholic dyspepsia, nervous derangement, alcoholic insomnia, organic deteriorations of the liver, kidneys, and lungs, alcoholic phthisis, alcoholic disease of the heart, cataract, calculi, nervous lesions, mental phenomena, loss of memory and speech, dipsomania, and transmitted disease.” He says it is neither a food nor a drink suitable for man’s natural demands, but that its application as an agent that shall enter the living organisation is properly limited by the learning and skill possessed by the physician.

This Society, on a former occasion, has fully discussed the social aspect of this question, when nearly every member took part in the debate, and the discussion is one of the most interesting in our Transactions.

On this occasion I wish, as briefly as I can, to refer to some of the physical and therapeutic effects resulting from the use of this agent, and first I would remind you of its vast importance in the laboratory. Out of 68 tinctures no less than 64 are prepared with spirits—40 with proof, and 24 with rectified spirit. There are also 16 so-called spirits, which are alcoholic solutions of a volatile oil. In the museum it is the agent in which specimens are preserved; and here we might refer to its great affinity for water—so greedy is strong alcohol for water that it extracts it from the muscle, tumour, or other tissue, while by its antiseptic quality it preserves the specimen from decay or change. The surgeon takes advantage of this quality, and by its rapid evaporating power inflammations and swellings are beneficially acted upon.

Spirit lotion, which means generally whisky and water, is even now among us a somewhat popular remedy. Its uses outside the body are both numerous and well recognised, but in the economy of the human subject its action is not so clearly seen, nor so well understood, yet it produces physical changes and mental phenomena of a very definite character. Most persons who are in the habit of using alcohol are familiar with the different stages of change which it produces in the animal economy.

Dr. Richardson very well describes the four stages thus:—"The first is a stage of excitement, when there exists a state of relaxation and injection of the blood-vessels of the minute circulation. The second is the stage of excitement with some muscular inability and deficient automatic control. The third is a stage of rambling, incoherent, emotional excitement, with loss of voluntary muscular power, and ending in helpless unconsciousness. The fourth and final stage is that in which the heart itself begins to fail, and in which death, in extreme instances of intoxication, closes the scene."

Alcohol enters the blood very readily when freely diluted with water, for which it has great affinity, and almost instantly produces its first characteristic effect of dilating the blood-vessels on the surface of the body by paralysing the nerves.

This stage is a most useful one if we could stop at it; for by this means fever heat is reduced in consequence of the increased quantity of blood exposed to radiation, and there results a marked diminution in the temperature of the body. But not only is the outer surface thus congested, the inner surface also is affected in like manner; and in this way a stimulus is given to a naturally weak or diseased organ to perform its function, for a time at least, under the influence of this spur. But the action does not stop here—it is progressive, and muscular inability quickly follows, unsteadiness of limb, with

incoherence of speech, sopor, and anæsthesia, leading on to the stage of drunkenness.

The primary action of alcohol on the internal organs and the brain is, I think, under the skilful direction of the physician, an important one in medicine; unfortunately, however, a great number of persons do not stop at this stage, but push its use to a degree which becomes injurious; and one of the characteristic effects of its use is, that it creates a craving for itself. They soon get to the brink of a precipice, over which not a few are precipitated. It is this peculiarity and this danger which makes the prescribing of alcohol so dangerous, and which gives rise to so many charges being brought against medical men for sanctioning its use. Now I consider that we have just as much right and liberty to prescribe whisky as arsenic, and that the patient has no more liberty to continue the use of the one than of the other without the knowledge and sanction of his medical adviser; and that if he does so it is purely at his own risk, and for reasons other than its therapeutic effects.

I wish now to state a few of what are supposed to be the good results arising from the moderate and medicinal use of whisky, and I go on the supposition that the alcohol used is the best matured and purest spirit to be obtained; for, during the last fortnight, while I have been experimenting with the samples before you, I have become very fully convinced that while some of the best may be taken with comparative safety, it is not so with other kinds. Even smelling at some of these whiskies will produce an aching pain in the cerebellum of a very depressing and continuous kind.

Another observation I may make—that in no instance are we to suppose that we are dealing with persons in good health. The finding of this Society on the occasion of the debate referred to was:—

"1st. That alcoholic stimulants are unnecessary in health.

"2nd. That their influence on health is only exceptionally beneficial.

"3rd. That their influence on health is generally hurtful.

"4th. That in order to lessen the hurtful consequences attending the use of alcoholic stimulants the Society advises that, if used, they should be in extreme moderation, only with food, not before dinner, and not habitually."

But all this leaves the question of their use in disease untouched. And first I would say, that in some cases of weak digestive powers the addition of an ounce of whisky at the mid-day meal seems to act with good results.

In phthisis I do not know any medicine so relished by the patient, as affording almost immediate relief to the breathing in the first instance, and where prescribed with milk as food it certainly does seem to arrest wasting, and often assists in restoring comparatively robust health; and its use in this form also

applies in most wasting diseases, especially those depending on a tubercular condition in children. In many of the various forms of disease of the heart, especially in the old, the use of alcohol is undoubtedly beneficial. In fevers, and at particular stages in the treatment of the disease, the beneficial effect of alcohol is recognised by most medical men. When dealing with the storm of delirium or the collapse of exhaustion it can be administered so as to act on the one hand as a sedative and on the other as a stimulant, serving as the steam does to the ship, battling with the head-wind of the tempest or propelling through the calm of the tropics, to carry her on only a little way where the trade-winds of a healthy breeze will leave her free to dispense with the auxiliary help. It is in these critical times that one has recourse to such an active agent without any questionings as to either its propriety or its expediency.

One of the common results of alcohol drinking is headache; but this is attributed generally to the impurities it contains, and I am inclined to believe they account for it to a large extent. The most characteristic effect of a moderate dose of alcohol, to me, is that it acts as a sedative to the brain and nervous system, and this effect is most marked on those who are not in the habit of using it constantly. Its stimulating effect on some persons is very evanescent, its sedative effect very prolonged. To such persons there is no work to be got out of alcohol—muscular debility and weariness soon sets in; if walking, they are unable to proceed on their journey, and if engaged in mental work, stupor and ennui supervene, their sensibilities are blunted, and a condition of easy lassitude results. I must now close this study, and I do so with a consciousness of the very imperfect way I have brought it before you, and under a deep impression that the investigation of this subject, from the very nature of it and from the many prejudices and preconceived notions about it, is beset with many difficulties, and the difficulties multiply as we approach a practical conclusion; yet I would venture to submit a few of what I think are plain facts derived from the considerations which have been before us:—

- 1st. That the value of a stimulant depends mainly on the quantity of alcohol it contains.
- 2nd. That where alcohol is prescribed whisky is perhaps the safest form in which to use it.
- 3rd. That the quality of the spirit is an item of importance as regarding its action, old being preferable to new.
- 4th. That in using whisky it should be freely diluted with water.
- 5th. That the habitual use of spirits is injurious to the animal economy.
- 6th. That it is a valuable agent in the hands of the medical profession in certain conditions of disease.
- 7th. That its use should not be continued after the results contemplated are attained any more than that of any other powerful and dangerous medicine.

Dr. Dill made a few remarks general.

Dr. Kevin thought it very questionable if whiskey should be used in phthisis.

Dr. Byers to read his paper the first thing next meeting.

(President) James Cuming

Seventh Meeting Session 1881–1882. February 14th '82.

President Professor Cuming in the chair, Drs. Fagan, Dempsey, Esler, McFarland, Smith (house surgeon), Whitla, Samuel Browne, Jnr. M.D., and several students.

Mr. Fagan exhibited an interesting specimen of osteomyelitis.

Dr. Byers read an interesting paper upon "The patella reflex phenomenon".

Paper:¹ In the year 1875 two celebrated German observers, Westphal and Erb, directed the attention of the profession to the great value, from a medical point of view, of a phenomenon long known as a schoolboy's trick. I refer to the peculiar jerk of the leg which takes place when the patellar tendon is struck. Charcot may have used the patellar-reflex in diagnosis before this period, but undoubtedly the profession at large was first made aware of its importance by the appearance of the papers of Westphal and Erb.

Since then the phenomenon has been studied with extraordinary care in its physiological, pathological, and clinical bearings by Westphal, Erb, Tschirjew, Burckhardt, Fürbinger, Schultze, Berger, Eulenburg, Charcot, Brissaud, and Franck on the Continent, and in this country by Grainger Stewart, Hughlings Jackson, Waller, Buzzard, and Gowers; so that, I think, no one will accuse me of exaggeration when I say that there are few symptoms of greater importance in the diagnosis of diseases of the nervous system than this patellar-reflex phenomenon, especially when it exhibits deviations from its normal condition.

The phenomenon has received many different names; it has been called "the patellar-tendon reflex phenomenon," "the knee-jerk," "the knee-reflex," the "knee phenomenon."

In this paper I shall—First, describe the phenomenon as it exists in a healthy individual, and mention several methods that may be employed to elicit its presence. Secondly, I shall state and examine the different views that have been propounded as to its physiological causation. Thirdly, I shall read the notes of a series of cases in which this phenomenon exhibited deviations from its normal condition, and I shall attempt in each case to account for such alteration.

First. You see in my friend (one of the hospital pupils) who is sitting with his right leg crossed over the left, and bent at an angle slightly greater than a right

¹ [Dublin Journal of Medical Science, 1882, v73, p186.]

angle, that when, with this stethoscope, which has an india-rubber ring round the pectoral piece, I strike the right leg just below the patella, immediately the foot is jerked forwards. Such is the phenomenon, and such is the ordinary method of testing for its presence.

The following plan is suggested by Buzzard if it is desired to ascertain the mere presence of the “patellar-reflex:”—“The patient, who is seated, plants his foot firmly down at such a distance that the leg forms a little more than a right angle with the thigh. Whilst the observer rests the palm of his left hand upon the patient’s thigh, he strikes with some implement held in the right hand several blows upon the ligamentum patellæ at about an eighth of an inch or so below the knee-cap. The quadriceps muscle can be felt, and (if the patient is in masculine garments) can be seen to contract more or less vigorously in response.”

The side of the hand can be employed as a percussor. If no response follows the blow the leg should be bared, and the observer should test most carefully by striking in the usual place, or on the patella, or the tendon above the patella, or the muscle itself, before assuming that the reflex is absent. In children, in whom there is often considerable difficulty in examining for the sign, I usually place them on a table with their legs hanging over the side, and while their attention is occupied in looking at a toy, a light tap on the patellar tendon is usually sufficient to demonstrate the presence of the phenomenon. The patellar-reflex is almost always present in health, although the amount of the contraction of the quadriceps muscle may vary at different times even in the same individual. Berger has examined 1,409 soldiers for this phenomenon, and has found it absent in 22, or 1.56 per cent, of these cases.

Although I have seen the patellar-reflex slight in several individuals, and absent in one—while in none of these when examined was there any evidence of disease—still I think that such cases are exceptional; and I am inclined to believe that the greater the care that is taken in testing for the sign the fewer will be the number of those in whom it is found to be naturally absent. With reference to those cases in which it is stated that the phenomenon is normally absent, it is of little importance, as Westphal thinks, to note in the case of any one that at a given time the patellar-reflex is absent, more especially if we know nothing of his history. The observation would be of much greater value if we could show that the phenomenon had disappeared. In some of these cases the absence of the patellar-reflex may be a premonitory sign of a spinal affection of which other symptoms will appear in the future. Again, in certain individuals the absence of the phenomenon may be owing to mechanical causes, Westphal having shown that it is difficult to develop the patellar-reflex in those in whom the tendon is very short, in those in whom there is a thick pad of fat under the tendon, and in those who are very stout.

Secondly. We shall now consider the physiological causation of the phenomenon. Two views have been suggested to account for it. According to one it is purely reflex—that is to say, that at the point where the observer strikes the leg, impulses are generated which travel up the sensory nerves to the cord, at about the level of the second and third lumbar nerves, and there undergo certain changes, of whose nature we are ignorant—except that as a result efferent impulses descend the anterior crural nerve to the quadriceps muscle, causing it to contract and to jerk forward the foot. According to the other theory the phenomenon is a local one, due to a direct irritation of the quadriceps muscle.

In support of the first view, advanced originally by Erb, and according to which the reaction is of the nature of a spinal reflex, evidence is forthcoming from two sources—(a) the experimental, and (b) the pathological.

(a.) As a result of experiments on animals (Fürbinger, Schultze, Tschirjew, Senator), in many of whom the patellar-reflex exists, it has been found that destruction of the portion of the cord in the lumbar region, with which the anterior crural is connected, or of the anterior or posterior roots of the spinal nerves in the same situation, or of the nerves to the muscle, is followed by a disappearance of the phenomenon.

(b.) In any disease in which the reflex nervous arc, at the situation mentioned, is injured, in either its sensory or motor portion the patellar-reflex is lost. This is exemplified in *tabes dorsalis* (Case I), and in *poliomyelitis anterior acuta* (infantile paralysis) (Case III.)

In favour also of the reflex theory is the fact that drugs which increase the irritability of the cord—i.e., strychnia, cause an exaggeration of the patellar-reflex; thus Eulenburg, in some cases in which the phenomenon seemed entirely abolished on one side, succeeded in making it reappear for some time by the hypodermic injection of strychnia, made in the neighbourhood of the *nervus cruralis*, or into the substance of the extensor muscles. On the other hand, medicines, such as bromide of potassium and opium, which diminish the irritability of the cord, lessen the activity of the phenomenon. Admitting, then, that the contraction of the quadriceps is of reflex origin, the question naturally arises—From what point do the sensory impulses arise when the leg is tapped; is it from the skin, the patellar tendon, or the muscle? That they do not begin in the nerves of the skin is clear from the following facts:—1. A light tap or push over the patellar tendon will not give rise to the knee-jerk. 2. If the skin is lifted up in a fold, so as to be quite separate from the tendon, and is then tapped, no contraction of the muscle follows. But, on the other hand, if the skin is divided and the blow struck on the exposed tendon the leg is immediately jerked forward; this experiment seeming to show that the irritation starts from the tendon—a view that gets additional weight from the circumstance that Sachs has

demonstrated the existence of nerves to the patellar tendon. But this view—viz., that the impulses arise in the nerves of the patellar tendon, is disproved by an experiment of Tschirjew. This observer divided all the nerves to the tendon patellæ in an animal, and, notwithstanding, a blow on it caused the muscle to contract. Further, in all cases in which a blow on the patellar tendon causes the muscle to contract, it must be in a condition of passive tension, and in some cases, as Erb has shown, sudden tension alone, as by quickly pushing down the patella, so as to make the quadriceps tense, will cause the appearance of the knee-jerk. Dr. Gowers has also shown that in certain cases in which the “tendon reflexes” are in excess a tap on the front of the leg will cause a movement of the foot. Here the stimuli do not act on the tendon but on the muscle.

So then we are compelled to believe that the stimuli arise in the muscle. But if this be granted Westphal's view that the contraction of the muscle is a local one may, after all, be the correct explanation of the phenomenon; and this theory is supported by the fact that Burckhardt, Brissaud, Tschirjew, Gowers, and Waller, who have examined the matter with great care, believe, as the result of their investigations, that the time which elapses between the blow on the tendon and the contraction of the muscle is shorter than it should be if the phenomenon was a purely reflex one. At the recent meeting of the International Medical Congress, in a discussion on his paper, Eulenburg gave his adhesion to the view that it might be a peripheral phenomenon. But if we adopt this explanation, how can we account for the absence of the phenomenon in those diseases which cause destruction of the reflex nervous arc?

Is there, then, any hypothesis which will reconcile these two opposing views, which will account equally well for the contraction of the muscle being a local one, and will yet explain the circumstance that any lesion which destroys reflex action causes a disappearance of the knee-jerk? The following explanation is given by Dr. Gowers:—“If,” he says, “we regard the contractions as local we have still to account for the irritability which permits the local stimulus to cause a contraction. This irritability is developed by passive tension. Hence I have suggested that the tension excites, by a reflex influence, a state of extreme irritability to local stimulation—such as that of a tap on the tendon, or such as the vibration from a tap near the muscle, or from a tap on the bone to which the tendon is attached—which thus excites a visible contraction.” I have endeavoured to give a full and fair account of the various views that are held as to the cause of this very remarkable phenomenon. Whatever view will eventually be found to be correct, the fact remains that this patellar-reflex phenomenon is of great value in disease, examples of which I shall now give in this the third part of my paper.

Case I.—*Tabes Dorsalis*; characteristic Ataxic Gait; Argyll-Robertson Pupil; absence of Patellar-reflex in

both Legs; previous history of Pains in the Legs, attacks of Indigestion, and Diplopia.—In Sept., 1881, I was consulted by a gentleman, aged forty-two, who gave the following account of his illness:—He was in perfectly good health until the year 1878, when he suffered from attacks of indigestion, accompanied with flatulence, especially after food. These attacks were not attended with vomiting, but during one of them he was much surprised one day, in looking out of the window, to find that each person passing along the street seemed to him to be double. This double vision was merely a temporary annoyance, but the attacks of indigestion have recurred at intervals up to the present time.

In 1879 he had pains in “the lower part of his back,” of a dull, heavy character, and in the spring of the following year he had also pains in his legs, specially in the back of the right leg, but also, though to a less degree, in the left. These pains have not been of a shooting character, but more like “rheumatic” pains. In the beginning of the year 1881 he first became unsteady in walking, and this unsteadiness was always worse at night. This was noticeable even to his friends at this time, for he states that one evening in coming out of the Turkish baths into the street his walk was so peculiar that a gentleman who was with him said, “You are like a drunken man, or are falling into paralysis.” From this time his heels in walking always touched the ground first. In the mornings, while washing his face (his eyes being then closed), he has a tendency to fall forward. Even before his movements became unsteady he had difficulty in going up and down stairs, and was obliged to keep a firm hold of the baluster. For some time he has had a curious feeling in his feet, “as if there were two or three folds of the sock under the sole of each foot.” He never noticed anything peculiar about his eyelids or eyes, with the exception of the double vision which I have mentioned.

Present Condition.—He is a very intelligent, large, well-developed man. He walks in the most characteristically ataxic manner, lifting his feet high, and bringing his heels down on the ground with a thump. He has great difficulty in starting to walk and in turning, his movements at these times being very unsteady. When he brings his feet together, and closes his eyes, he begins to sway from side to side, and would fall if not supported. In both legs, from the knee downwards, he feels the prick of a pin, and a heated knife when in contact with the skin, merely as tactile sensations. There is no wasting of the muscles of the legs, and when lying on a sofa he moves the legs freely in any direction. That the tabetic incoördination has extended to his upper extremities is shown by the apparent difficulty he has in buttoning his waistcoat. His pupils are very small; they do not respond to light, but act during accommodation (Argyll-Robertson symptom). There is no ptosis or strabismus. He has great difficulty in distinguishing

blue from green wool. There is no visceral mischief of any kind to be detected in the chest or abdomen. Patellar-reflex absent in both legs.

In the above case, when seen by me, the diagnosis was so clear that the absence of the patellar-reflex was of assistance principally in corroborating the other symptoms; but the great value of the symptom is in the early stages of *tabes dorsalis*, before the ataxic gait has become developed, and then it is frequently associated with the lightning pains. Of the very great importance of the absence of the patellar-reflex in *tabes dorsalis*, Dr. Buzzard, one of the most recent writers on that disease, thus speaks:—"Let me say then at once that, in my judgment, we may take it that Westphal's test, the absence of the knee-phenomenon, provided that this is associated with good voluntary power and ideo-muscular contraction of the *vastus internus*—a provision which Dr. Erb has most strongly and justly insisted upon—is a nearly certain sign of *tabes dorsalis*. I am prepared indeed, from something which I lately saw, to meet with the absence of the knee-phenomenon as possibly representing the only symptom of *tabes* in a certain case."

In fifty cases examined by Erb the patellar-reflex was absent in all but one, and he thinks that it is probably always an early symptom. In his experience it is never absent in young or middle-aged people in health, and hence he thinks that its absence may be regarded as almost pathognomonic of *tabes* in its earlier diagnosis.

The lesion in *tabes dorsalis* is sclerosis of the posterior columns, or, to state the matter more correctly, of that portion of these columns known as the "posterior root-zones" (Charcot), involving the posterior roots on their way to the posterior cornua. This lesion causes an interruption of the sensory impulses in their passage to the spinal centre, and so the patellar-reflex is lost. Even without our knowledge of the morbid anatomy of *tabes*, we would almost be warranted in concluding that the motor portion of the reflex arc was intact, from the fact that good voluntary movement of the lower limbs is preserved, and absence of any wasting of the muscles; while, on the other hand, that the sensory portion of the loop is affected, is apparent from the lightning pains and the anæsthesia.

Westphal thinks that there is a particular part of the posterior columns which, when diseased, causes the disappearance of the patellar-reflex; and, as bearing directly on this question, I will give a short resumé of a case, an account of which he brought before the Medical Society of Berlin.

A man, thirty-two years of age, in whose family there were numerous examples of different kinds of nervous affections, was brought in 1877 to the Charité Hospital, Berlin. He had been blind for six months, being merely able to tell, and that only with his left eye, day from night. He was a pronounced hypochondriac,

with all sorts of hallucinations. He had no symptoms of *tabes*, neither irregular movements, nor anæsthesia, nor lightning pains. In October, 1879, the patellar-reflex disappeared on the right side. He gradually got worse, and died in January, 1880. A few days before his death the "patellar-reflex" was gone on the left side—it continued absent on the right.

At the autopsy, in addition to very advanced degeneration of the optic nerves, optic tracts, and corpora quadrigemina, a yellow zone or strip of degeneration was seen in the centre of the posterior columns of the cord distinctly marked off from the neighbouring parts. The situation of this region of degeneration in the posterior columns was altogether peculiar. It attained its maximum on a level with the lumbar part of the cord. The cornua, columns of Goll, and posterior roots, were intact. Westphal infers from this very unique case that the loss of the patellar-reflex in *tabes dorsalis* is due to a lesion involving a definite zone in the centre of the posterior columns of the lumbar part of the cord. This observation of Westphal is particularly interesting as probably representing in some cases of *tabes* the first pathological change in the spinal cord, and as explaining the early absence of the patellar-reflex. Charcot had previously been led to assume that the sclerosed bands in *tabes* are slender and narrow so long as the lightning pains are the only symptoms present; as these areas of degeneration enlarge both outwardly and inwardly, the tabetic incoördination is observed. If there is marked anæsthesia, the posterior roots and posterior gray cornua are involved; while, finally, if the sclerosis extends to the posterior part of the lateral columns, the clinical picture is represented by paralysis (with or without contracture), the advanced stage of the malady. As to those case of *tabes* in which the patellar-reflex is said to be present, Westphal thinks that some of them are not genuine cases of *tabes*, while in the case of others it is possible that the patellar-reflex may disappear late in the course of the disease, indicating that the central portion of the posterior columns has also been involved at a late period.

Case II.—Diphtheritic Paralysis; absence of Patellar-reflex; complete Recovery, and subsequent return of the phenomenon.—On August 24th, 1881, a lad, aged fourteen, was seen by me in the out-patient room of the Children's Hospital. He stated that about six weeks before his legs became weak and unsteady in walking, and at times "seemed to give way under him at the knee-joints." There had been no pains in the legs, but for a time his feet had been "numb and dead," and in walking at first he could not tell whether the ground in contact with his feet was smooth or rough. There had been no symptoms referable to the bladder or rectum. He was now, he said, much better, and had been improving for the last two weeks. The numb feeling, had quite left his legs, and he had no difficulty in walking.

Present Condition.—He can move his legs with perfect freedom; there is no wasting or flabbiness of the muscles, and no anæsthesia. The patellar-reflex is absent in both legs. There is no loss of the power of accommodation, or any other eye symptoms. The condition of the palate is normal, and there is no evidence of any form of paralysis to be detected. On questioning him more closely I learned the following facts, which explained the nature of the case:—Three months before I saw him he had a “very bad sore throat,” and was so ill and weak that he was obliged to remain in bed for a fortnight. Soon after getting up again his mother noticed that his voice had become altered, and “was as if he was speaking through his nose.” At this time he began to have difficulty in swallowing, and he says that frequently, on taking milk, part of it would return through his nose. After having been up for a week he went back to work, but did not remain long, as, owing to a pain in his side—due, he thinks, to exposure to cold—he was obliged to take to his bed a second time. During all this time the difficulty in swallowing continued. While lying in bed the second time he was very much surprised to find that in reading the newspaper he was obliged to hold it at a much greater distance than usual from his eyes, because when he brought it closer “the letters,” as he puts it, “seemed to run into one another and to become indistinct.” He mentioned this circumstance to his friends, but they could see nothing wrong with his eyes. After being in bed for a week he got up, and sometime afterwards his legs began to get weak. His arms have never been affected. I did not see him again until January 26th, 1882, when I found that the patellar-reflex was present in both legs. He said he was quite well, and at work every day as usual.

It is plain that this boy suffered, in the first instance, from a diphtheritic sore throat, which was followed by paralysis of the muscles of the soft palate and pharynx (shown by the nasal tone of voice, the difficulty of swallowing, and regurgitation of milk through the nose); of the eye (in this case the ciliary muscle was involved, as was evident by his inability to read the paper when held close to his eyes, the letters being then indistinct, while he could manage to read it when it was held further off); and of the lower extremities (indicated by the weakness of the legs, the difficulty in walking, the anæsthesia, and the absence of patellar-reflex).

In connexion with this case the following remarks of Buzzard are, I think, very apt, when, in speaking of *tabes dorsalis*, he says:—“There is one pathological condition, however, which may possibly give rise to some doubt—indeed, I have met with an instance in point. In diphtheritic paralysis there is often a tottering gait, accompanied by numbness in the extremities. If there should be, as sometimes happens, no difficulty in deglutition, and no failure of the power of accommodating

the eyes, a strong superficial resemblance to a case of *tabes dorsalis* is presented. In such a case the patellar-tendon reflex will, in all probability, be absent, and the vastus internus muscle may contract as freely as in health to direct percussion. The acuteness of the symptoms, however, the absence of the characteristic lightning-pains, and the history of preceding sore throat should be sufficient to distinguish this condition from *tabes*.”

In this case, when first seen by me, the only symptom present was the absence of the patellar-reflex. The previous history, however, showed that it had been a case of diphtheria with paralytic sequelæ—a diagnosis which was confirmed by the ultimate return of the patellar-reflex phenomenon.

Several observers have noticed, within the last two years, the absence of the patellar-reflex in cases of paralysis following diphtheria. Any explanation, however, of the cause of this strange occurrence would involve, in limine, a discussion of the causation of diphtheritic paralysis itself, which is still, I am afraid, far from being settled.

Some recent pathological researches, however, throw very considerable light on the subject. Thus, Dr. Abercrombie examined very carefully the spinal cord and medulla of seven fatal cases of diphtheritic paralysis. The only pathological changes detected were in the gray matter of the anterior cornua, and they consisted in a swollen condition of the large motor cells. “The margins of these are very ill-defined, and the processes have in most instances entirely disappeared. The contents of the cell have a granular aspect, and the nuclei have disappeared, or, where still visible, are highly granular.” These changes occurred in limited areas.

M. Déjérine has described the changes met with, in three fatal cases of diphtheritic paralysis. They were the same as those described by Abercrombie, but more advanced.

These observations seem to indicate that the paralysis may be due in part to the subacute myelitis. If the cord is affected in the lumbar region the reflex arc would be interrupted, and accordingly the patellar-reflex would be lost. It is very difficult, however, to explain the return of the phenomenon, as one would expect, if the cord was affected by a myelitis, that the patellar-reflex would be permanently absent, as we know it is in poliomyelitis anterior acuta.

Another view as to the cause of the paralysis which follows diphtheria is that which is suggested by Buhl. He found in a case that the spinal nerves were thickened at their roots, and that the sheaths of the nerves were infiltrated with lymphoid nuclei and cells. “His view is that in certain cases these infiltrations lead to thickening of the connective tissue, which in turn contracts, and so compresses the nerves. According to him the nerve symptoms appear when the constricting

effect of the thickening of the connective tissue begins, they remain while it lasts, and disappear finally when the thickening diminishes." This hypothesis of Buhl would account for the disappearance as well as the subsequent return of the patellar-reflex in diphtheritic paralysis.

Case III.—Poliomyelitis Anterior Acuta; Wasting and Paralysis of certain Muscles of Left Leg; absence of Patellar-reflex.—A lad, five years of age, was brought to the Children's Hospital in December, 1880. The relatives said that two years before he had been "hot and sick for a few days." On recovering from this illness they noticed that his left leg was "useless." They had tried various remedies, with little effect.

Present Condition.—The left leg is smaller and colder than the right. There is also wasting of the muscles of the leg, and partly of those in front of the thigh. When he walks the leg is dragged, and there is a tendency to talipes equino-varus. The left knee-joint is very movable, and the bones of the left side seem smaller than the corresponding ones on the opposite leg. The patellar-reflex is present in the right side—absent in the left. Sensibility is retained.

In this case the absence of the patellar-reflex is due to the destruction of the multipolar ganglion cells in the gray matter of the anterior cornua (the essential anatomical lesion in poliomyelitis anterior acuta), interrupting the impulses in the motor portion of the reflex arc. The wasting of the muscles and their paralysis show that it is the motor part of the loop which is involved, especially as the absence of any loss of sensation indicates that the sensory part is intact.

The absence of the patellar-reflex in poliomyelitis anterior acuta is of great diagnostic value, as it distinguishes that disease from paralysis depending on cerebral causes, the patellar-reflex in the latter being either exaggerated or not altered at all.

Case IV.—Right Hemiplegia; Contracture of Right Arm; increased Patellar-reflex of Right Leg, and exaggerated "Supinator-reflex" of Right Arm.—I have at present under my charge, at the Ulster Institution for the Deaf and Dumb and the Blind, a girl, thirteen years of age, who was paralysed at the time she was admitted into the Institution. I have not been able to ascertain the previous history.

Present Condition.—She is deaf and dumb, and is hemiplegic on the right side. There is no rigidity in the leg, but the arm is kept close to the side, the elbow-joint is bent at a right angle, the wrist-joint is flexed, and the fingers are firmly closed. The arm can be extended only after some force is used. The patellar-reflex is very much exaggerated in the right leg. On tapping the tendon of the right supinator longus, the hand is immediately jerked toward the shoulder. There is no paralysis of the face or tongue.

In cases like the above the exaggeration of the patellar-reflex may be due to the withdrawal of the normal

inhibitory action of the brain, owing to rupture of the pyramidal tract, but against this explanation of the phenomenon is the fact that the exaggeration of the patellar-reflex is not, as a rule, noticed immediately after the lesion in the brain, but seems to require some days to elapse before it can be observed. Seeing that the exaggerated patellar-reflex is often associated in these cases with late rigidity (a phenomenon depending on descending degeneration of the pyramidal tracts in the lateral columns), some think that the increased tension of the muscles under such conditions may give rise to a condition of irritability in the terminations of the nerves, which, in turn, increases the excitability of the spinal centre. But this is clearly not the real explanation of the exaggeration of the patellar-reflex in these cases, as the phenomenon appears long before there has been time for the occurrence of degeneration in the cord. No explanation thoroughly satisfactory has yet been given to account for the exaggerated patellar-reflex in these cases.

J. Moore

Eighth Meeting Session 1881–1882 was held upon Tuesday the 28th inst 1882 February.

Present, Professor Cuming in the chair, Dr. John Moore, McConnell, Kevin, Dempsey, Smith, Jnr., Whitla, J. W. Browne, Wadsworth, McKeown, and Workman, Stewart.

Dr. Dempsey read a paper upon the management of pregnancy, labour and puerperal state. He raised the most interesting debate.

Paper:¹ IN this paper I shall only touch upon a very few points in connexion with pregnancy, labour, and the puerperal state: to do more would be to write a system of midwifery. I am aware that even in thus dealing with my subject I must open up an extensive field for discussion, perhaps too much so for any useful purpose. But there are some modes of procedure in obstetric practice which from experience I have adopted, and this communication is more for the purpose of testing their accuracy and eliciting the opinions of the members for my own information than for putting forward any new theories. None of them would individually warrant me in occupying a meeting of the Society in their discussion, so I have placed them under the three heads stated in the title of the paper.

The Vomiting of Pregnancy.—This is, perhaps, one of the most troublesome and unsatisfactory complaints we have to deal with. When it is severe, and incessant the patient's life is placed in great danger from starvation; even in a moderate degree it causes a great deal of inconvenience and discomfort to the patient, and anxiety and trouble to the medical attendant in his endeavour to arrest it. It is pretty generally admitted to be a

¹ [Dublin Journal of Medical Science, 1882, v74, p171.]

reflex act depending upon some altered or diseased condition of the uterus or cervix. Dr. Graily Hewitt regards it as due to flexion or version of the uterus, causing a cramped or tense condition of the uterine fibres at or in the region of the internal os, and consequently his treatment of the complaint is reposition of the uterus. Dr. Henry Bennett and Dr. Clay, of Manchester, say it is due to congestion, inflammation, or erosion of the os or cervix, or both; and they treat it with the local application of nitrate of silver. On the other hand, Dr. Marion Sims and M. O. Jones, of Chicago, hold it is due to some kind of reflex irritation from the cervix, and that its cure will be effected by setting up inflammation by means of caustics at this site, and thus concentrate the nervous phenomenon at the point of irritation, and in that way relieve the stomach. The late Dr. Copeman, of Norwich, had an infallible belief in dilating the os with the finger, and thus relieving the tension of the cervix, which he believed to be the cause of the vomiting.

Professor Tarnier, by the introduction of a vaginal plug, arrested the vomiting of pregnancy, which result he attributed to the steadying action which it had upon the uterus. But, for various reasons, when a patient first consults us regarding vomiting occurring during the pregnant state we are scarcely justified in having recourse to any of these modes of treatment, or in even making a vaginal examination at all, provided, of course, there has not been total failure from the adoption of medicinal remedies. As a general rule, we must first exhaust these before we have recourse to operative remedies. I have never had occasion to dilate the os, or to cauterise it, or to replace the uterus for the cure of vomiting. No doubt in some cases I have had to try a variety of medicinal agents before the desired effect was produced, but latterly in the use of ingluvin in 5-grain doses three times a day I have been pretty successful in the treatment of this complaint. If time permitted I could cite a large number of cases in which bismuth, morphia, hydrocyanic acid, bromide of potassium, oxalate of cerium, and some others were tried without benefit, and in which ingluvin at once arrested the vomiting. Of course I have also had cases in which this remedy appeared to have very little effect, and in which others were more beneficial, but, on the whole, I have had more satisfaction and better results from its use than I have ever had from any other remedy. Inguvin is an American preparation made from the gizzard of the hen. It is therefore a kind of pepsin.

If we might found a post hoc argument upon the good effects of this drug in the treatment of the vomiting of pregnancy we might conclude that the disease is not in all cases of nervous origin depending upon reflex irritation from the uterus, but is in some cases a veritable dyspepsia, probably arising from the altered condition of the circulation and the quality of the blood during pregnancy.

Adherent Placenta.—In 1835 Sir J. Simpson drew attention to inflammation of the placenta. The symptoms, he thought, were not well marked, but pains in the uterus and painful movements of the child created a presumptive evidence of its existence. The most marked symptom is, I believe, a constant aching pain, confined to one point. I think where a pain of this character exists you can almost say with certainty that there is inflammation at the placental site, and you will most likely have a retained placenta. Dr. J. Henry Bennett, in a paper to the British Medical Journal in 1875, casually pointed out this connexion. Even in cases in which the placenta has naturally come away after the existence of pain of this kind, I have always found it hard and fibrous to the feel, and, from its appearance, creating a doubt in my mind whether it had come away entire or had left small patches behind. The frequency with which these cases are followed by offensive lochia and feverish symptoms leads me to think that minute portions of the placenta do remain behind, adherent to the uterine wall. With patients who suffer much from uterine pain during pregnancy I always come prepared to their confinement for retention of the placenta, and a short time before the termination of the labour I give a full dose of infusion of ergot, in the hope that the firm contraction thereby set up may break down adhesions and expel the placenta.

There is no operation that one should be more slow of performing than the removal by the hand of an adherent placenta. The only maternal death I have ever had that I believe depended upon operative interference was after the removal of an adherent placenta. There was very great difficulty in peeling it off, and though I believe I brought it away entire the patient died of septicæmia on the seventh day after labour. I formerly thought nothing of removing an adherent placenta before that occurrence if there was any delay, but now I prefer to wait and to give a good dose of ergot, with the hope of effecting its expulsion.

Forceps.—There is still some difference of opinion as to the application of the forceps, especially in what is called the high operation when the head is at the brim. When the head is low down, the os fully dilated, and labour progressing slowly, authorities are pretty unanimous in recommending its speedy termination by the use of the forceps as a safe and justifiable proceeding for both mother and child.

However, in the high operation when the head is at the brim and the os not fully dilated there is considerable difference of opinion as to the use of the forceps. Some hold the operation should not be performed until the os is fully dilated, others that it may be performed as soon as the os is sufficiently open to permit of the application of the blades, provided, at the same time, that it is soft and dilatable. If the os is hard and rigid all are agreed that the operation should not be performed, at all events, until by the use of hot baths, chloral, chlo-

roform, or some other agents, the rigidity has been overcome.

When other indications for the use of the forceps exist I do not wait, if it is soft and dilatable, until it is fully dilated. The operation, if carefully and slowly performed, will assist the process of dilatation, and I have never known it to do any injury. Recently, in consultation with Dr. M'Harry, I performed the operation with great ease in a case in which the diameter of the os was not more than an inch during the pain, and where there was barely room to introduce the blades. Of course in this case the parts were all soft and lax; the patient was dying comatose of tubercular meningitis; she was in the seventh month of pregnancy; the child was living, but the pulsations were becoming weak; and we thought it was a most justifiable proceeding to make an effort to save the child—and in this we were fortunately successful.

When the bony pelvis is contracted from deformity, but not to such an extent as to preclude all hope of delivering a living child with the forceps, it is usually recommended to leave the case to natural efforts for some hours, even after the rupturing of the membranes. It is said these efforts, if they do not effect delivery, will so mould the head as to make it pass more readily on the application of the forceps.

This is a point upon which I am not satisfied. If the bones of the foetal head are feebly ossified, if the fontanelles are large and open, and the sagittal suture also open, and easily traced from one fontanelle to the other, some moulding of the head and overlapping of the parietal bones will undoubtedly take place, with consequent reduction in its size.

But if the fontanelles are small, and ossification of the bones firm, and very slight possibility of overlapping of the parietal bones, the moulding which such a head will undergo in a slow difficult labour will be more apparent than real, and will be due to the lengthening out of the head from the development of the caput succedaneum.

If any moulding or reduction of the foetal head does take place it is counterbalanced by the dryness and tumefaction of the soft parts which are sure to set in, and which make natural and instrumental delivery much more difficult and dangerous to both mother and child. I was forcibly impressed of the necessity of early operation in a case which I attended in the year 1877. The patient was a small rickety woman, not much over four feet in height. It was her fourth confinement; the three previous ones were instrumental, and the children dead born.

A very large projection of the promontory of the sacrum, which inclined to the left side, was discovered on examination. It was so near to the vulva that on first touching it I thought it was the child's head coming down on the perineum. The head was, however, in front of this, and high up; the membranes were intact; the os

was about three quarters dilated, but soft and dilatable; the soft parts were all moist and in good condition; the head was presenting in the first position.

I stated at once that natural efforts would not effect delivery, that I was afraid I would require a consultant, but that I would first try the use of the instruments myself. I ruptured the membranes, and managed to get the forceps nicely locked over the ears. By forcible traction during the pains, and loosening the blades in the intervals, so as to relieve pressure on the head, I at length brought it through, and she was delivered of a living child.

It was only then I learned that the three previous deliveries were craniotomies; that she was usually two or three days ill; had two medical attendants each time, and that all had expressed their opinion that delivery at term of a living child would be an impossibility; and that for her own safety, if she again became pregnant, premature labour should be brought on at the seventh month. My success in this case, I believe, depended upon early operation, when the parts were moist and afforded every facility for the gliding over them of the head. She was only about three hours ill. I have since attended her in confinement, but found more difficulty; she had been longer in labour before sending for me. I delivered her with the forceps, but the child was dead, or rather died immediately after birth. Since the above was written I have again attended this patient, and by early operation delivered her of a living child.

Dr. Playfair, in speaking of the risk to the mother in labour obstructed by a contracted pelvis, says—"The long-continued and excessive uterine action produced by the vain endeavours to push the child through the contracted pelvic canal, the more or less prolonged contusion and injury to which the maternal soft parts are necessarily subjected (not infrequently ending in inflammation and sloughing, with all its attendant dangers), and the direct injury which may be inflicted by the measures we are compelled to adopt for aiding delivery, all tend to make the prognosis a matter of grave anxiety." Now in the first part of that paragraph there is a general acknowledgement of the evils to the mother attending delay in obstructed labour, and in the second part the injury inflicted on the mother by the means we are compelled to have recourse to when natural efforts fail is only hypothetical—it may or may not take place.

When it is admitted that delay is attended with such injury to the soft parts as inflammation, sloughing, and their consequences, should we not endeavour by timely interference to prevent this injury being done? I think we should, unless there be a greater danger occasioned by interference. But as this interference is needed in the long run in the majority of cases, is it not as likely to produce then the same or, perhaps, greater injury than if it had been undertaken early? Again, in referring to the risk to the child in protracted labours, he says:—

“Even in cases in which the contraction is so slight that the labour is terminated by the natural powers, it has been estimated that one out of every five children is stillborn; and as the deformity increases in amount, so, of course, does the prognosis to the child become more unfavourable.” In the interests of the offspring it is therefore clear that there should not be too much delay in the labour; and the statistics of Dr. Johnston, of the Rotunda Lying-in Hospital, and others, show that the timely application of the forceps lessens very considerably the infantile mortality.

When, therefore, the conjugate diameter is about three inches (and in the case I quote it was not more), and there is scarcely a hope that labour will be terminated by the natural efforts, and if the os is dilated or dilatable, I would wait for no moulding, believing that the compression exercised by the forceps and the moist and lubricated condition of the soft parts will amply compensate for this deficiency, and will give a better chance of a live birth, and do less injury to the mother.

Even when the disproportion between the pelvis and the foetal head is slight, and there is a fair possibility of labour terminating naturally but slowly, I think we are justified in assisting nature by the use of the forceps.

Those cases in which the cavity of the pelvis is deep and the tubera ischii approach close to each other, labour is usually difficult, painful, and slow. Pelves of this kind are often met with in this town among the working classes, and delivery is usually effected in the end by the forceps. Occipito-posterior positions of the child are also usually difficult and slow; and in these two latter cases I do not delay too long, because from experience I know that in the majority of cases the forceps have to be had recourse to in the long run. I have never seen any harm result from the timely use of the forceps, and in the last 500 cases of midwifery of which I have a record I find I used them fifty-five times, or once in about every nine cases.

The Application of the Binder.—The proper application of the binder is a matter, I believe, of very great importance, and yet very little reference is made to it in works on midwifery. The only directions regarding it are to pull it well down over the trochanters and hips, and to put it on comfortably tight.

Very often it is pulled down too low, and this not only prevents the patient from being able to pass water, but it also interferes with the free egress of the lochia, and may thus from retention cause putrefaction and septicæmia. It should be only so low as to give it a sufficient hold to prevent it slipping up around the waist.

Again, I have found that the pad, the use of which most obstetricians recommend, has occasionally an injurious effect. If, as directed, it is placed immediately over the uterus and the binder tightened on it from below, it will either slip over the uterus, or it will push the uterus before it high up in the abdomen.

If anyone takes a small hard pad and places it on the uterus, immediately above the pubis, and firmly tightens the binder upon it, you will find that it will shoot the uterus upwards in the abdomen. I have on several occasions, on my first visit after confinement, found the uterus lying at the margin of the costal cartilages in either hypochondriac region.

In such cases there was always considerable secondary hæmorrhage, and I thought the position depended upon the relaxation of the uterus which generally accompanies hæmorrhage. I afterwards saw that it was the faulty application of the binder and pad which gave rise to both these conditions. The following case is an example:—

I attended Mrs. F. in her first confinement last August. She had an easy labour, and a twin birth. Before applying the binder the uterus was firmly contracted, and there was little loss. I left her in a very satisfactory condition. Five or six hours afterwards a messenger came to say she was very faintish, and had a great loss. On loosening the bandage the uterus was found lying up under the right costal cartilages, and the pad in a position below it. I pressed the uterus down into its place, and the hæmorrhage ceased. Several other cases of a similar kind have come under my notice, and all were attended with secondary hæmorrhage of a trickling kind. I need not mention the evil effects likely to follow upon the enlargement, and the filling up of the interior of the uterus with clots—after-pains, inflammation, and septicæmia are the most immediate, subinvolution and displacements are probable remote effects.

The pad, if used at all, I think should be placed above the uterus, and not upon it, and care should be taken in pinning the bandage not to stretch it too tightly on a line immediately over the uterus, because the uterus not being so likely to go downwards will go upwards, and free itself from the pressure.

Dr. R. Moore proposed [by] Dr. McFarland seconded by the Secretary.

James Cuming, President

Ninth Meeting Session 1881–1882.

Present, Professor Cuming in the chair, Dr. Harkin, Workman, Core, Fagan, Byres, McConnell and Whitla, (Dr. S. Browne, Jnr.).

Dr. R. Moore was unanimously elected a member of the Society.

It was resolved that the books and periodicals recommended by the Council should be got for the Society (vide report of Council 11/3/82).

The Honorary Secretary was directed to procure copies of the two Bills before Parliament (relating to infectious disease) and to submit them to Council.

It was also resolved to ask the Librarian to find out the missing and back numbers of the New Sydenham

Society and to supply the lists to Dr. Byers who kindly consented to order them for the Society.

Dr. Core read a paper on a case of land-scurvy.

Paper:¹ SCURVY, which in past ages was such a human scourge that we find it stated as probable “that it has been more destructive to mankind than any other disorder,” is now so rare, at least in civil practice, that I thought the notes of the following case might not be uninteresting—masked as it was at first, and the diagnosis obscured by an injury.

The ætiology of the disease still being unsettled renders it also desirable that any case which might assist in the determination should be recorded.

On the 16th December, 1879, I was requested to see W. A., a locomotive engine-driver, who, I was informed, had sustained an injury at the Northern Co.’s Railway. On visiting him I learned that some days before he had been standing on the upper step of his engine, the weight of the body resting on the toes of the left foot, he holding on by the handrail. His foot slipped off the step unto another similar one about two feet lower, when he felt as if something had given way in his leg, coupled with a sharp burning pain. He was able, although with difficulty, to remain at his work for a week, when, finding himself getting worse, he sent for me.

On examination I found the injured limb semiflexed, a hard swelling in the popliteal space, and reaching half way down the muscles of the calf, the skin extensively ecchymosed, part of the discoloration being recent and part fading away. There was slight tenderness. He not only made no other complaint, but said his health was as good as usual. His face was of an ashen hue, but as I knew his colour was bad at the best I paid no attention to that.

I was astonished that he had been able to walk about so long after what the signs appeared to prove had been a considerable rupture in the muscles of the calf. My astonishment, however, carried me no further in my investigations, and I prescribed strict rest for the limb, and an evaporating lotion. Under this treatment no improvement took place, fresh effusion occurring from time to time, while the old discoloration faded away. On attempting on one occasion to get out of bed a fainting fit occurred, lasting long enough to cause serious alarm.

So matters were, when at one visit I saw a new ecchymosis situated in the hollow beside the tendo Achillis, quite unconnected with the original seat of injury. Guided by this ray of light, I found enough in a few seconds to establish the diagnosis of a well-marked case of scorbutus, a disease now so rare in this potato-eating country as perhaps to palliate its being for a time overlooked. There were extensive ecchymoses at both ankles, at the gluteal folds, and reaching down the thighs, as well as brawny swellings in both hams, with

contraction of the hamstring muscles. The gums were spongy, rising up so as almost to hide the teeth, and bleeding when touched; the breath foetid; pulse 120 and weak. When asked why he had never complained about his mouth, he replied that he had attributed its condition to having given up smoking when he took to bed, and did not think it worth while to mention it.

A piece of characteristic information now came out—vis., that the patient had for some time thought that his skin must be getting very thin, as he could hardly dry his face with an ordinary towel without drawing blood.

His diet had always been, as he thought, of the most liberal kind, consisting of plenty of beef and mutton, bacon, eggs, bread and tea, oatmeal porridge and milk. For twenty years, however, he had not eaten potatoes, except a few each autumn when they were new, and from the time he had come to Belfast to live, about three years before, he had eaten neither these nor any other fresh vegetable.

The diagnosis being clear, the prognosis was confident and reassuring, and the treatment easy. Plenty of mashed potatoes and other antiscorbutic vegetables, with lemon juice ad libitum, made in a few days a marked improvement.

No further ecchymoses took place, the old ones gradually disappeared, the gums regained their normal condition, and strength returned. The hard swellings behind the knees and the contractions of the hamstring muscles remained longest, but these, too, disappeared, seemingly assisted by occasional faradisation, so that he was able to resume work after having been absent eleven weeks.

In this case, but one of the many, circumstances which at various times have been supposed to be causes of scurvy was in operation. The patient, a well-to-do mechanic, was temperate in habit, always warmly clad, had from the nature of his employment an exceptional amount of fresh air, was accustomed to a good allowance of animal food, was subject, as far as I could make out, to no depressing influences whatever—all these favourable circumstances, however, being inefficient in maintaining health, fresh vegetables being wanting. The latter having been supplied, recovery at once took place.

Mr. Fagan read notes of a case of tumour of the pharynx and showed the patient.

He also showed a patient from whom he removed a large lymphatic gland over the carotid region.

It was resolved to pay the porter £1-1-0 for his serving in connection with the Society room for the present session.

The Secretary read a letter from Professor Dill who was unable to be present, in which he promised a paper on accidental hæmorrhage for next night.

George F. Wales

¹ [Dublin Journal of Medical Science, 1882, v74, p339.]

Tenth Meeting Tuesday 28th March 1882.

Present, Dr. Wales (in the chair), Dr. John Moore, Professor Dill, Drs. Esler, Dempsey, Mackenzie, Workman, Dr. S. Brown, Jr., Dr. McConnell, Dr. Harkin, Stewart, R. Moore, J. W. Browne.

Dr. Murray brought the matter of a petition to Parliament in relation to Medical Officers' Superannuation (Ireland) Bill. This was referred to the Council.

Professor Dill exhibited an abnormal placenta and afterwards read a paper upon "Accidental hæmorrhage and its relation to other uterine hæmorrhage".

Dr. J. W. Browne exhibited a bony plate of the choroid.

James Cuming, President

Eleventh Meeting Tuesday April 18th 1882.

Present, Professor Cuming, Dr. Wheeler, Dr. K. Wheeler, Esler, Workman, S. Browne, McFarland, O'Neill, Dill, and Dr. Whitla.

In the absence of Dr. McKeown the Secretary showed a patient upon whom he operated for a large tumour of the orbit.

Dr. McFarland read a paper upon recruiting.

Paper:¹ *THE subject of Recruiting is not one of much importance to the medical profession in Belfast, as there is a military dépôt here where recruits are at once seen and examined by a military medical officer. I selected the subject for the last meeting of the Ulster Medical Society, as I thought some of our brethren from other towns would be present, who frequently have to examine recruits, and to whom the following hints might be of use, or, at any rate, would be calculated to put them on a good understanding with their military brethren.*

Very frequently recruits are passed in country towns by civilian practitioners, sent up to the dépôt for approval, and there rejected as unfit for the service. Now, when this happens repeatedly, the civil doctor feels his dignity hurt, and sometimes imagines there is an animus on the part of the military surgeon. It is no unusual thing to see him come up to the dépôt to ask the meaning of all these rejections. The truth is that the military surgeon is not actuated by any animus, nor has he any feeling of dignity on the subject, but simply has to protect himself from an official scrape.

The rule of the service is that the approving medical officer must be a military surgeon on full pay. This does not mean that he is more competent than a civil doctor, or than a military surgeon like myself on retired pay; but it is that the authorities can call him to account if he passes bad recruits in a way that cannot be done to us. He may be removed from his appointment, declared to be inefficient, or punished in various ways.

Once a recruit comes before a military medical officer for approval, that officer is solely responsible for

him. Whatever correspondence takes place afterwards is with this military surgeon. If a man is found to be under height or under chest measurement on joining his regiment, the officer commanding is bound to report the fact to the Commander-in-Chief, who then calls upon the officer commanding the dépôt where the recruit was approved for an explanation why the recruit was passed into the service under the regulation size? The officer commanding the dépôt then calls on the approving surgeon, who has then to defend his position as best he can.

If a recruit is declared unfit from other causes—say defective sight, not being able to see the target at the required distance—a medical board is ordered to assemble, and if the board declares the recruit to be unfit for the service, the military surgeon is called upon to explain why he approved of a recruit who was afterwards declared to be unfit for the service by a board of medical officers—a very difficult and unpleasant question to answer.

You will see from these remarks that it is of vital importance to a military surgeon that his recruits are not objected to. Written rules are laid down by Government on the subject; but like an operation in surgery, it is one thing to know how it is done, but another thing to do it practically. By following the rules I will now give there is little chance of recruits being objected to on joining their regiments.

There are two sine quâ non rules which must be observed. One is, the recruit must be examined perfectly naked, and the other that the surgeon make the examination himself. I will illustrate the first rule by one case that occurred to me out of many of the sort. I found a young soldier in the ranks of a regiment I had charge of lame and unable to march. He had bunions and deformed toes. On questioning him as to how he passed the doctor, he told me the doctor was in a hurry, and that he was stripped all to his stockings! No doubt the recruiting sergeant made him keep them on!! It is most essential that a line soldier should have good feet. There is just one pattern boot worn by the infantry; it is called the ammunition; it is the best worn by soldiers of any European army, but a man must have good feet to wear it. They are, of course, made of different sizes, and are used in all climates. A soldier may be served out with them when on active service, and, of course, must be able to wear them at once. The man I speak of could not wear the ammunition boot at all. Secondly. The approving surgeon must examine the recruit himself, as otherwise he may be imposed upon. In any case he must be in a position to say, if the recruit should be objected to, that he examined the man, and found so and so. It will not do to say he saw the man examined, or was present.

In examining a recruit, there are two men the doctor must beware of. One is the recruiting sergeant, and the other the recruit himself. The recruit will make the

¹ [Dublin Journal of Medical Science, 1882, v74, p255.]

most of himself when he wants to enlist—stretch himself up when measured for height, try to swell himself out when measured for chest; but, by-and-by, when he joins his regiment, and begins to repent of the step he has taken, he will make the least of himself. Commanding officers like to have big men in their regiments, and are only too glad to report if recruits are under the standard measurements. Directly the approving military surgeon signs a recruit's attestation paper passing him, the recruiting sergeant gets one pound in cash. These fellows are as wily as foxes; they know that a recruit is taller in the morning than evening, so if he is a little under size they will keep a lad in bed a couple of days, and bring him straight over to be examined, so as to gain perhaps the required half inch. A recruit with varicose veins to any extent is ineligible. A recruiting sergeant will bandage him up to the last minute. Recruits must be eighteen to twenty-five years of age; they will smarten up a man of thirty, make him shave off his whiskers, get his hair cut short, assume a juvenile air, and swear he is only twenty-five. The surgeon is responsible for a recruit's apparent age.

The examination of a recruit and filling up of his attestation paper takes seven or eight minutes, and should be done in the following way:—First, take a good look at him, stripped; if he has inveterate skin disease, marks of scrofula, syphilis, bad varicose veins, rupture, adherent cicatrix, or deformity, reject him. If not measure him for height. This is done by making him stand on the measuring standard; put one end of a tape measure under his heels, keep a steady pull on the other end. If he rises on to his toes the tape will come from under his heels, and you will know it. If he has a great thatch of hair on the top of his head take off a quarter of an inch for it; bring the horizontal beam right down on the top of his head, and read off the measure from the index.

Next take the chest measurements. Make the recruit put his hands over his head, put the measuring tape on the inferior angles of the two scapulæ behind, then make him slowly let down his arms and count ten, and at the same time the surgeon draws the tape together across the chest when the recruit counts ten. This is the Government rule, but I have found from experiments that a man can count ten without any diminution of the chest; but make him count twenty, and, at fifteen or sixteen, he will catch his breath—that is the time to draw the tape together, and you will get his true measurements. The lower edge of the tape should rest on his nipples in front.

Next for the limbs. Make him kick out with both legs alternately, hop up and down the room on either feet, springing lightly on the toes; bend the ankle-joints and toes of each foot alternately, kneel down on one knee, up again, then on the other, then on both, springing up upright; then turn round, separate the legs, stoop and touch the ground with both hands, the knees being

straight. In this position it will be seen if the recruit has piles, or fistula, &c.; rise up, turn round, stretch the arms up with hands over the head, cough forcibly. Examine in this position for hernia or weak inguinal rings, also for varicocele—varicocele to any extent with dependent testicle is a cause for rejection. This completes the examination of lower extremities. Examination of upper extremities is done by making the recruit swing round one arm and then the other, to test shoulder-joints; then strike out both fists, to test elbow-joints; then press elbows to sides, with forearms flexed, and rotate forearms; then bend wrists, twist them round and round, open and shut fingers, to see if any are stiff or deformed; flex thumbs on palms of hands, and extend alternately; there must be perfect use of fingers and thumbs. This completes examination of upper extremities.

The heart and lungs are now to be carefully examined with the stethoscope to ascertain their soundness; any abnormality is cause for rejection. The recruit is to be asked if he has ever had fits of any kind. Mouth is to be carefully examined to ascertain if he has a fair set of teeth, throat free from ulceration, palate sound, &c. The ears are to be carefully examined, also the cranium and the eyes. The test dots, War Office Form 1233, are to be used for examining the sight. The recruit must be able to tell the number of dots at the required distance (15 feet) with each eye, one being covered while the other is being examined. This part of the recruit's examination must be performed with the greatest care and circumspection; it is of the utmost importance.

Of no less importance is the next part of the examination—which is conversation with the recruit. The surgeon having placed the recruit at a distance holds conversation in a low tone of voice, to test his hearing powers by the recruit's answering; the surgeon will observe if there is any hesitation in his speech, and if his intellect is good. The recruit is also to call out in a loud voice "Who comes there?" It is of the utmost importance to ascertain the mental state of the recruit; the only guide, most likely, the surgeon will have will be the appearance of the recruit, and his answers to questions.

This, gentlemen, is the ordeal to which any approving military surgeon will subject a recruit; and civil practitioners may rest assured that unless the recruit can satisfactorily pass through this ordeal he will be declared unfit for the service.

He showed two patients, brother and sister, affected with Duchenne paralysis.

Paper:¹ DR. M'FARLAND at the same time showed two interesting cases of pseudo-hypertrophic muscular paralysis occurring in a brother and sister. Both were very typical cases. The father of the children had been

¹ [Dublin Journal of Medical Science, 1882, v74, p258.]

Ulster Medical Society
Session 1881–1882
President James Cuming

confined in an asylum, but was now employed as a porter. He seemed of very inferior intelligence, and very reticent, or else very stupid. This relationship with a father of unsound mind was considered to be a point of great importance in the case.

James Moore M.D. Chairman
2nd May 1882

LIST OF MEMBERS, 1ST MAY, 1882
WITH THE DATES OF THEIR JOINING THE SOCIETY.

HONORARY MEMBERS (elected in 1881).

SIR W. MAC CORMAC, F.R.C.S.E., E.R.C.S.I.
J. W. MOORE, M.D., F.K. & Q.C.P.I.

MEMBERS.

1877—ANDERSON, R. J., M.A., M.D., M.Ch. (Q.U.I.)
1836—ANDREWS, PROF. T., M.D.Ed., L.R.C.S.Ed., F.R.S.
1872—AICKIN, W., M.D. (Q.U.I.), M.R.C.S.E., L.A.H.D.
1868—BECK, F. E., F.R.C.P.Ed., L.R.C.S.Ed., L.A.H.D.
1843—BECK, J. W., M.D.Glas., M.Ch. L.A.H.D.
1868—BROWNE, J. W., B.A., M.D. (Q.U.I.), M.R.C.S.E.
1842—BROWNE, S., M.R.C.S.E., L.K. and Q.C.P.I.
1879—BURDEN, H., M.A., M.D., M.R.C.S.E.

1877—WORKMAN, CHAS., M.D., M.Ch. (Q.U.I.)

Twelfth Meeting was held upon Tuesday May 2nd 1882.

Present, Dr. James Moore in the chair, Professor Dill, Dr. Wales, Snr., McFarland, Esler, Workman, Core, Mackenzie, Johnston, McKeown, Fagan, John Moore, and Whitla, and Wadsworth, Kevin, Robert Moore.

Dr. McKeown exhibited some specimens of puff-ball and made some remarks about its hæmostatic qualities.

Professor Dill showed a valuable and most interesting series of rare and new midwifery forceps and made an able explanatory statement.

Dr. Core give an account of a case of rupture of the uterus.

Paper:¹ ON the 12th April last I was requested to see R. A. M., a married woman of thirty-six years of age, pregnant for the ninth time and expecting her delivery in about a month. She had that morning a slight "show," some pains, was frightened, and hence the summons.

¹ [Dublin Journal of Medical Science, 1882, v74, p338.]

On examination *per vaginam* I found the os uteri undilated, the cervix hard, thickened, and fissured, and the head presenting. There being at the time neither hæmorrhage nor uterine action, I prescribed rest in bed, and two grains of opium. I left, giving directions that I should be sent for when labour set in. At ten o'clock on the following morning I learned from a messenger that there had been pains and some loss during the night, but that neither had been such as to cause the woman to wish me to be sent for. I arranged to call at eleven o'clock, the messenger having been instructed that there was no urgency. On calling I found from the patient herself that the pains had been pretty constant and pretty severe for about two hours, but that from about ten minutes before my arrival none had occurred. She was restless, but did not make any complaint, and the bed being in a dark and nearly inaccessible recess in a badly lighted room, I did not at first notice anything particular in her appearance, and up to this time neither the patient nor any of those around her had any idea that there was anything in her condition more than ordinary.

On making an examination I found the os two-thirds dilated, and occupied by a soft mass, feeling rather like a placenta, but which further investigation proved to be a clot. Not being able to reach the head, which the previous day had been presenting, I passed my hand over the abdomen, and was easily able to make out that nothing intervened between it and the fœtus but the abdominal wall. That a rupture of the uterus had taken place, with a partial escape of the fœtus into the abdominal cavity, was unfortunately only too apparent; and as collapse was slight I decided, after sending for assistance, to administer a dose of ergot, and deliver as speedily as possible. This was done in a few seconds by turning and without any difficulty, the fœtus being dead and considerably decomposed. In the hope, rather than expectation, of ensuring contraction and thereby stopping hæmorrhage, I introduced my hand into the womb, found that the placenta was lying loose in the abdomen, having passed through a rent in the anterior wall near the fundus, through which also a hernia of the intestines had taken place. There was no contraction, and the placenta was easily removed. Half an hour after delivery was completed death took place. I found, on referring to my obstetric case-book, that on February 29th, 1880, I was asked to see the same woman, who was said to have been for a considerable time in labour, the expulsive efforts having been very forcible and frequent, but quite ineffectual. After examination I caused her to assume a dorsal position, which, by rectifying an extreme anteversion of the womb, allowed the labour to proceed quickly and naturally to its termination.

On making subsequent inquiries I learned that for the last four months of the pregnancy which ended fatally, Mrs. M. had been in bad health, which dated

from a tedious attendance on one of her children who died. During these months she had suffered from a fixed pain, which, from description, appears to have been at the fundus of the womb. The comparative ease, so to speak, with which the rupture in this case took place is noticeable, the actual rent not having been preceded by any violent uterine action, and not being accompanied by pain or by any sensation of anything having given way. Taking the circumstances of the previous confinement into consideration, and remembering the state of health of the patient during the preceding four months, it would seem that ordinary uterine action, rendered ineffectual probably by a want of parallelism between the long axis of the womb and that of the inlet, and to some degree also by a hypertrophied cervix, was too great a strain upon the muscular tissue near the fundus (weakened at that part by a localised metritis) which consequently, to use a graphic phrase, tore like wet brown paper. The exact pathological condition is unknown, no post mortem examination having been allowed.

James Moore M.D. Chairman
14th November 1882

Annual Meeting Session 1882–83 was held upon July 11th 1882.

Present, Professor Cuming President in the chair, Professor Dill, Drs. Wheeler, Snr., Whitaker, Aickin, Mackenzie, McFarland, John Moore, Byers, Workman, O'Neill, Dempsey, Whitla, Wadsworth, Kevin, Esler, J. W. Browne.

The President showed a patient suffering from severe chronic spasm of the neck.

Dr. Dempsey read notes of a case of ascending paralysis.

Paper:¹ Acute ascending paralysis is a disease of such comparative rarity that I believe the details of the following case will be found interesting to the Society.

Rev. A. B., aged thirty-six, of dark complexion and feeble constitution, was seen by me on the 14th of March, 1882.

Previous History.—He had an attack of typhus fever about eleven years ago of a very severe nature, and from which he made a slow recovery. From that time he had shortness of breath and a slight cough, and from my own knowledge he had crepitus at the apex of his left lung for seven years. This appeared to be stationary, and did not give him much trouble. He was able to attend to all his duties, which latterly were of an onerous nature—in fact he was doing the work of a fellow-clergyman as well as his own. Previous to his illness many of his friends remarked that this extra work was telling upon him. About the middle of February he had to attend some cases of small-pox, and, being afraid of

¹ [Dublin Journal of Medical Science, 1882, v74, p341.]

the disease, he asked me to re-vaccinate him, which I did on the 21st of February with calf lymph. It took well, and ran through the usual course—the scab falling off a day or so before my visit to him on the 14th of March.

His present illness commenced on the 5th of March with a cold in the head and in the chest—with cough and expectoration. An eruption of herpes appeared at the same time on his mouth and nose. He felt generally out of sorts, but was not so ill as to necessitate his remaining in bed or even in the house. He attended to his clerical duties, though not so much as usual, but this was more because of the unsightly eruption on his face than of his unfitness for the work. His appetite was not affected. On the morning of the 10th of March, while shaving, he remarked a numbness and want of sensation in his fingers. He could not feel the razor in his hand. This numbness was felt in the thumb and the two first fingers of both hands, and extended as high as the wrists. Numbness was also felt along the backs of the thighs and legs, and in the soles of the feet. On Sunday, the 12th of March, with these symptoms unchanged, he officiated twice, and in the evening preached for nearly an hour. He felt very much exhausted after this effort. The next day he was a little better, and, the day being fine, he went out for a long walk. He attributed the numbness in the legs to bad circulation, and he thought a good walk would make him all right. He walked very fast for about four miles, but did not feel his feet touching the road. The sensation was similar to that of walking on deep snow. He was thoroughly exhausted when he came home, but eat a good dinner. Before going to bed he took a large dose of Eno's fruit salt, which acted several times during the night. He rested very badly—felt hot and uncomfortable, and perspired very freely. However, perspirations had been very profuse for the last two or three nights.

The following day I found him sitting at the window with a newspaper beside him, which he had been trying to read, but the letters after a time became so blurred and indistinct that he was obliged to give it up. This temporary defect of vision was the only one complained of during his entire illness. The conjunctivae were congested, and the pupils moderately contracted. This condition of the pupils remained throughout. The conjunctivae, however, in a day or so became normal. His face was deadly pale, and the expression worn and haggard. From the beginning he had neither dizziness, headache, nor pains in the back or legs. Pressure on the spinous processes did not cause pain. His legs and hands were quite cold, though he felt a burning heat in them. His grasp was moderately firm. The patellar tendon reflex was present. On getting him to walk I noticed slight unsteadiness in his gait. He lifted his feet well off the floor, but let them down in a tremulous clumsy way, somewhat like an ataxic patient. He complained of great weakness in his legs and back. Pulse was 74, and temperature 98°; tongue was coated with a light yellow fur

in the centre, red and moist at the edges and tip. There was no disturbance of the bladder. He passed water freely, which was loaded with lithates, but was free from albumen. Breathing was hurried, and there was dulness and crepitus at the left apex, and moist râles scattered through both lungs. Expectoration was thick, and slightly rusty in colour. The heart's sounds were healthy and regular, but the pulsations were forcible and visible over the front of the chest. His mind was perfectly clear. I prescribed bromide and iodide of potassium, a mustard foot bath, a large mustard blister to the back, and rest in bed.

March 15th.—Pulse 70, temp, normal. Spent a very restless night. Complains of an intolerable burning heat in the legs and up along the spine. This was the most annoying symptom he had, and it continued during the remainder of his illness. He also complained of burning heat in his mouth, but he had no thirst. The weakness in his legs is increasing. He attempted to get out of bed in the morning, but fell on the floor. He can draw his legs fully and quickly up to him in bed, or move them about, and he can raise his arms up or move them in any direction, but his grasp is much more feeble than it was yesterday. I got him out on the floor. He raised himself off the bed with great difficulty, and when up could not stand without support. His legs were very weak and gave way under him, and this was especially the case when he attempted to turn on the floor. This effort to walk quite exhausted him. Patellar reflex is present, but more feeble. Has some difficulty in swallowing today—some tea taken quickly came back through his nose. There is no paralysis of the face, and he protrudes the tongue in a straight line, and there is no difficulty of speech. During the night had a sharp boring pain in the head; it only lasted for a short time, and was the only actual pain which he had anywhere during his entire illness. Sensation was impaired, but not lost. Contact with the skin was delayed in perception, and this was especially the case in the lower parts of the legs. Sensibility was not further disturbed during the disease. The cough was troublesome owing to the accumulation of phlegm, and there was an evident inability to expectorate it though it was quite loose. I had the advantage of Dr. Cuming's assistance in the case today. The bowels not having acted since, we prescribed a brisk purge, and the bromide was reduced in quantity and the iodide increased, while derivatives were applied along the spine.

March 16th.—Pulse 60, temperature normal. Had one hard motion this morning. Has difficulty now in drawing the legs up to him, and there is less power in the arms. Sitting up and turning in bed are becoming impossible without help. No muscular twitchings or spasmodic manifestations in the extremities, nor pain on touch or pressure anywhere. The difficulty of swallowing is increasing; urine is passed freely; perspirations have ceased.

March 17th.—Pulse 60, temp. 98°. During the night was almost suffocated with the secretion which accumulated in his chest, and which he was unable to expectorate. Cannot turn or raise himself in bed. Legs are quite lax, and the greatest efforts only cause the slightest movement in them. They offer no resistance to passive movements, and exhibit no kind of tension or twitchings. If fully flexed upon the abdomen it gives rise to slight pain. The patellar reflex is completely absent in both legs. Arms can still be raised off the bed in a tremulous zigzag way. He is no longer able to grasp the hand. The respiration is still more embarrassed, but the movements of the diaphragm are unimpaired. Deglutition increasing in difficulty. Speech is slightly thickish, but the mind is perfectly clear. At 4 p.m. his pulse was 58 and very weak. Deglutition had become so difficult that he was almost unable to swallow anything.

When then with him I gave him a pill. After a long time he got it down, but was uncertain of the fact, and insisted on me examining his mouth to see if it was not still in it. Respiration was very much embarrassed, and he was making constant but ineffectual efforts to expectorate. There was now complete paralysis of the legs, but he was still able to move the arms a little. The bowels have never acted, though repeated purgatives have been administered. The functions of the bladder are still unimpaired. There is no paralysis of the face, he can shut his eyes, and corrugate his eyebrows. There was no appearance of bed-sores.

He died at 7.30 p.m. He was wanting to get out of bed, and his legs were pulled over the edge for him. He was raised a little up, but immediately expressed a wish to be let down again, and he quietly expired. That was the eighth day after the first symptoms of numbness, the fourth day after the first indication of motor paralysis, and the thirteenth day after catching cold.

Remarks.—We had not the advantage in this case of verifying our diagnosis by a post mortem examination, but the history and symptoms of the disease were so well defined that I think we were justified in founding a positive diagnosis upon them. A post mortem examination, however, in this disease has not revealed in any case yet reported any anatomical changes in either the spinal cord, the medulla oblongata, the brain, the sympathetic nerves, the peripheral nerve trunks, or the muscles.

In the spinal canal, where the symptoms would lead one to expect to find evidence of anatomical change, nothing of an abnormal kind has been discovered.

Neither hyperæmia, myelitis, destruction of ganglion, or of nerve fibres has been found by any of the methods at present available for pathological investigation, so that the disease must be due to some impalpable disturbance of nutrition of so fine a nature as to escape detection.

However, Dr. Ross, of Manchester, in his work on "Diseases of the Nervous System," publishes a case

which was diagnosed as acute ascending paralysis, and in which, on post mortem examination, the central column, the median area, and the central group of ganglion cells, were found to be diseased. "The diseased areas showed granular degeneration of Gerlach's nerve network, complete disappearance of the ganglion cells, increase of nuclei, and dilatation and congestion of blood-vessels." But this patient, who was a female, was not seen by Dr. Ross during life, and the history given of her illness is somewhat imperfect.

The absence of paralysis of the sphincters was one of the strong points which we relied on in distinguishing this disease from acute central myelitis. In the latter disease it is often the first symptom which attracts attention, or if not it generally sets in early in the disease. The functions of the sphincters of the bladder and rectum were perfect until the last; indeed, in the case of the latter, obstinate obstipation was one of our greatest difficulties in the treatment—due, no doubt to paralysis of the abdominal muscles and the muscular coats of the intestines.

Again, the character of the onset of the attack and the gradual progress of the disease were different from the usual course of acute myelitis. Its inception was marked by none of the severe disturbances of sensation or of motion which generally characterise the beginning of the latter disease. There were neither muscular spasms, contractions, fibrillar twitchings, nor even pains, during the entire course of the illness, and the sensation was only very slightly impaired.

The progress of the disease was also characteristic of acute ascending paralysis, as first described by Landry, and more recently by Westphal. It slowly crept over the body, without fever, delirium, loss of intelligence or memory, or the development of decubitus, and finally attacked the functions of the medulla oblongata, producing paralysis of deglutition, asphyxia and death.

The condition of the patellar reflex is a point of importance in the present case. There is only one case reported by Westphal in which it was found lacking. In our patient, with the advance of the disease it gradually became extinct, and on the last day of his illness was entirely absent.

In acute myelitis there is early failure of all reflex actions. In the latter disease there is also a rapid development of acute bedsores—a complication which did not arise in the present case.

From acute myelitis disseminata the distinction is not so easy; however, in it, too, there is generally paralysis of the sphincters and spastic symptoms, but often it is impossible to decide the question positively without the aid of a post mortem examination.

In the causation of the disease, catching cold, mental and physical exertion, and some others, are mentioned. In the present case cold, fatigue, and residence in a damp house, are most likely to have contributed to the production of the disease, but there is a possibility,

perhaps a probability, that the vaccination may have been the exciting cause, or at least that it may have had something to do with its ætiology. The infection of variola is said to exercise a great influence in the production of acute myelitis. May not the vaccine virus, in a constitution already lowered by conditions seriously affecting the nervous system, have a similar effect?

If the vaccination in this case had anything to do with the production of the disease it would strongly favour the theory put forward by Westphal, Landry, and others, that acute ascending paralysis is a disease depending upon some intoxication of the blood—because what more likely channel of entrance for bacteria into the blood than by inoculation with calf lymph from an unhealthy animal.

The present is the first case of this special form of disease which I have ever met with, and I think that—even without the light which a post mortem examination would have thrown upon it—it is deserving of record.

The Honorary Secretary read the report of Council. Its adoption was moved by Dr. Wheeler, Snr., and seconded by Dr. Whitaker and passed.

The Treasurer read the report of the financial state of the Society which showed a balance of £64.11.4 in hand. Moved by Professor Dill and seconded by Dr. Workman and adopted.

Dr. Dempsey read a report of the Library which on the motion of Dr. Moore seconded by Dr. Esler was adopted.

It was moved by Dr. Whitla seconded by Dr. Aickin that a special meeting of the Society be called by the Council after they have considered Dr. Dempsey's report and prepared a scheme for the Library.

The office bearers were then elected.

Dr. McKeown **President**

Drs. David Johnston and Aickin **Vice-Presidents**

Dr. Whitla **Honorary Secretary**

Dr. Esler **Honorary Treasurer**

Dr. Workman **Pathological Secretary**

Dr. Dempsey **Librarian**

Council: Dr. McFarland (13), Byres (9), Dill (9), Fagan (9), Mackenzie (9), Wadsworth (9).

Drs. Kevin and O'Neill appointed **Auditors**.

J. Moore 17th July 1883

ULSTER MEDICAL SOCIETY

SESSION 1882–83

First Meeting was held upon November 14th 1882.

Dr. James Moore occupied the chair, afterwards vacating it for the President Dr. McKeown. There were present Dr. James Moore, John Moore, Wheeler, Snr., Professor Dill, Drs. J. W. Browne, McConnell, Nelson, Wales, Esler, Dempsey, Whitla.

The President delivered an able and eloquent address and on the motion of Professor Dill seconded by Dr. Wheeler the best thanks of the Society were accorded to the President for his eloquent and original address.

Paper:¹ *We have been taught from our earliest days, and with most people it is almost a matter of belief, that though merit and worth, whether of individuals or classes, may be neglected or despised, yet sooner or later they are certain to obtain recognition, and to secure for their possessors all the honours, distinctions, and emoluments to which their character, genius, and usefulness entitle them. The medical profession has, I fear, reason to be sceptical of the general truth of this comforting idea. They have been waiting very long and very patiently. From the earliest times in the history of this country no member of the medical profession has been deemed worthy by the Sovereign to be elevated to the same dignity as the members of the church, the bar, the army, and the navy. The bright days of royal favour have not yet reached us. The majority of our most distinguished men, who have spent their whole lives in the service of humanity, and have done work which will bear fruit as long as the records of civilisation endure, have, as a rule, closed their career without any honorary distinction whatever. I do not think that any honour in the power of the Sovereign to bestow would have added any lustre to the name of a Hunter, a Jenner, or a Harvey; but still, that honours should be lavished on other professions whilst the medical profession is overlooked, is a matter for grave dissatisfaction. Had the late Sir James Simpson been a Frenchman doubtless our neighbours, who love to honour merit, would have conferred upon him senatorial honours. Lister—whose patient and laborious researches have revolutionised surgery, made operations, formerly perilous, now comparatively safe, almost banished from hospital the scourges of the surgical wards, diminished vastly the death-roll after all surgical operations, and gained for himself imperishable laurels—would, long, long ago, in any other monarchical State under the sun, have received the highest distinction. But, I ask seriously, has the profession, in pursuit of its just claims to equality,*

followed the path known to lead to preferment? Has it not shown too little self-assertion, too little professional, and an entire want of public spirit? It has had little political influence, because it never tried to have any—it has had, until quite recently, no organisation—it has never shaken a throne or displaced a minister—it has never been a factor to be taken into account in practical politics.

What reason, therefore, had it to expect aught but the reward usually accorded to those who meekly submit to neglect and injustice? To solve the problems of life and disease, and combat decimating plagues, may earn for the physician undying renown; but, to secure proper recognition by the State, the members of the profession must do as the ambitious of every other profession have hitherto done. I should not at all touch upon this question of honours were it not intimately associated with the question of the greatest possible good to be accomplished by the profession for the community.

I do not doubt that, to the philosophic mind, it will appear that a life spent in the quiet, conscientious performance of professional duties, free from the turmoil and bustle of public life, is the best and happiest of all. Were all men, however, to take this view our Social organisation, the result of ages of experience, would crumble into dust. We must have public men, and I hope to show that, in the interests of the State, we should have public medical men.

You will gather from what I have said my opinion as to the cause of this extraordinary and long-continued neglect. It is not merit alone which counts in the race for royal favour—it is political service, political power. Efficient public service cannot be rendered nor political power secured except by obtaining seats in Parliament. If Harvey, Hunter, Jenner, and others, have been the investigators and discoverers, where, may I ask, are the medical legislators to give prominence in our statutes to the lessons of their teaching, and where the medical administrators to give practical effect to such legislation in every corner of the empire? We want in our ranks legislators and administrators. To have chief administrators we require that medical men should be trained in the great school of public affairs. It is surprising how few members of the profession occupy seats in Parliament. I know that to a provincial practitioner it is practically impossible to pursue successfully his profession and devote a large part of his time to Parliament.

But why do not many of the most eminent metropolitan doctors, who have enormous incomes and large fortunes amassed, seek to obtain positions of public influence out of regard for the welfare of the people? Their advice on all legislative matters touching the general health of the community would be certain to command the attention of Parliament. Continuous attendance would not be at all necessary, and their

¹ [Dublin Journal of Medical Science, 1882, v75, p114.]

professional pursuits would not be interfered with so much as supposed. But, even were some loss incurred, surely many members of the medical profession would be found ready to make some sacrifice, like other members of the community, for the public weal, and to follow the example of the late Sir Dominic Corrigan and of Dr. Lyons, the able representative of the City of Dublin. If the profession only think of adding fee to fee, and do nothing more effective in the interest of the State than tender unsolicited advice, then how can they reasonably expect any honour whatever when ministers are besieged by persons whose votes may either make or unmake a ministry?

How grievously the public interests have suffered from the want of medical members of Parliament, it is impossible to overestimate. Let us take the sanitary laws in operation in Ireland as an example. By an Act of Parliament passed only a few years ago, the dispensary medical officers were forced, under pain of dismissal, to accept the position of sanitary officers at salaries to be fixed by the boards of guardians. They derive a large part of their incomes from private practice, and self-interest, therefore, naturally suggests that they should not take sanitary proceedings which would tend to the rupture of friendly relations with their private patients. Their public duty and their private interests are, therefore, directly antagonistic. How, then, can it be expected that, by sanitary reports and legal proceedings, they should incur both ill-will and loss of income—and this, too, for a mere pittance of £10 to £20 per annum?

Both the salaries paid and the officers selected rather lead to the suspicion that it was never meant that our sanitary laws should be really effective. I wish to do the officers every justice. Perhaps, under the circumstances, no body of men could have been found to have acted with more independence and more in the interests of the public. But the whole system is a blunder; and if we are to have the health of the people really looked after, the sooner it is supplanted by an efficient one the better. Indeed into the mind of man a more absurd idea could not have entered than that of making practising dispensary doctors the sanitary officers of the country.

What immediate advantages might be expected from the presence of twenty to thirty medical members of Parliament? Parliament would then have on the spot, and in a position of influence, men who, speaking generally, would be up to the current knowledge of epidemic and other diseases—their causes, modes of propagation, and the measures necessary to stamp them out; and who would be familiar with the general agencies actively at work undermining the health of the people. Further, medical men know more of the conditions of life of all classes, from the lowest in the social scale to the very highest, than perhaps any other class in the community, and I would confidently expect that

any legislation to which medical men actively contributed would bear the impress of the very widest sympathies. But let me particularise a little the vastness of the interests of the nation in an effective sanitary system, which, be it remembered, can only be brought about by the earnest work of the medical profession. I have not the statistics of the United Kingdom before me, but you all know that hundreds of thousands die annually from preventable diseases. Try to estimate the loss to families and the loss to the State by the untimely death every year of this vast army of persons, who are either bread-winners, or have had large sums expended in their maintenance and education to make them bread-winners.

Our losses in war from the weapons of war in the last half century would not probably equal the preventable mortality in a single year. But sanitary affairs are of importance not only to the civil community, but to our offensive and defensive forces. The great question of the health of the army and navy, on which not only our prestige as a nation but our very existence may sometime or other depend, is one especially for medical men. What is the use of a sick army? It is of more importance to have our men well fed, to protect them from unsanitary conditions—and they are legion—than to provide them with rifles a little more or less accurate in aim, or quick in discharge. The sanitary service should be a distinct service in the army, and should be entrusted to medical officers having nothing else to do—all sanitary orders being subject, of course, to the approval of the superior military officer. Besides these very important matters, there are others in which medical men would be able to give opinions more reliable perhaps than any other members of the community—for example, our poor-law, hospital, and asylum administration, protection of infant life, Contagious Diseases Acts, quarantine laws, the Acts relating to the Infectious and Contagious Diseases of Animals, and our Food and Drugs Acts. Further, medical legislators would be expected to have an influence in promoting scientific research by adequate endowments, and I would not confine that research to any one field. It should embrace not only diseases of man and the lower animals, but of plants. Surely it might well repay the nation to prosecute experiments on an extensive scale to ascertain fully the natural history of the potato disease, to find out a remedy more or less efficient, or to warn the people of all the circumstances of a local or general character which influence it. I do not know of any subject of more direct importance to Ireland. This disease so lessens the food-supply as to lead from time to time to a veritable famine, and is to be charged with no inconsiderable part of our social disorders. The discovery of a remedy for the potato disease would be of more material advantage to the people than many deep-sea dredgings or expeditions to observe the transit of Venus!

Ulster Medical Society
Session 1882–1883
President William Alexander McKeown

But now, leaving the general questions, I revert to sanitary affairs to consider the machinery for carrying out sanitary laws. I would say that with a body of medical members, animated by one spirit, the Government would probably be induced to consider seriously the advisability of creating without delay a great State Department of Health with a Cabinet Minister and a subordinate or two with seats in Parliament. I know of no measure of more importance to the whole community, or one which would give greater satisfaction to the profession. Indeed I note this as a happy omen—that the profession is quite unanimous on the question, and that we only need some activity and the appearance of a number of additional able parliamentary champions to secure attention to our views. I believe that we are on the eve of vast and beneficial changes. We are drifting fast to the era of preventive medicine—then a large proportion of members of the profession will be engaged in the prevention, a more congenial occupation than the cure, of disease.

The chief places in the administration of such a State Health Department, or at least some of them, should be filled by those best suited by previous training to deal with all the questions involved—viz., medical members with good capacity for organisation and general management of affairs. The present sanitary officers should be relieved of duties which they never sought, and which they accepted only through the compulsion of the Act of Parliament. The whole kingdom should be divided into large districts, each district having a chief medical officer with assistants, all to be appointed and removable by Government, so as to secure that independence of local interests without which no sanitary system will ever work satisfactorily. These officers should all be legally qualified practitioners with diplomas in State Medicine, and should be required to devote the whole of their time to sanitary work in its broadest sense. The chief sanitary district officer should have some legal training and should hold the commission of the peace. He should be empowered to hold sworn inquiries when to him it should seem fit in all sanitary matters of importance, such, for example, as the cause, progress, and avenues of dissemination of epidemics. All new houses should be inspected and certified by himself or one of his subordinates as fit for habitation before occupation; the sewerage and water supply arrangements should receive his special attention. To inquire into all matters affecting, immediately or remotely, the health of the whole or any section of the community, should be within the functions of the sanitary officers.

Although I have only spoken of the advantage to the public arising from the accession of a large number of medical men to the parliamentary ranks, and the creation of a great State Department of Health with its officers in every district of the kingdom, we cannot close our eyes to the fact that the profession would

thereby derive much dignity and honour. I doubt not also that, with such a department, the medical profession would furnish more aspirants for parliamentary honours than at any previous time, and that the too well-merited reproach of want of public spirit with which the profession has been so often charged would soon be a thing of the past. Let us hope that we may soon have in our British Parliament representatives of medicine not less distinguished than the late Nélaton in the French and Virchow in the German Chamber.

But now I proceed to the second branch of my subject, and one which, though it may seem to bear directly on the mutual relations of the members of the profession to each other, yet involves the great question of the elevation of the profession in the highest degree. Dr. Thompson, the late President of the North of Ireland Branch of the British Medical Association, delivered some time since an admirable Address. He detailed a scheme for the defining of different grades of the profession and regulating fees. No doubt he had given the matter much attention, and all must concede that he dealt with the question in a very able manner. As you are all quite familiar with his views, I shall not enter upon any explanation. I think his proposals hardly adapted to the circumstances of the time. My chief objection to his scheme was this, that I did not conceive it possible to bring about such a change by any spontaneous action of the medical profession. The profession will, in my opinion, only be reformed and advanced by action from without. The self-interest of the public is the lever I would use. Law has seldom been reformed by the spontaneous action of practising lawyers, and Church reform has been very seldom the work of clergymen. I trust this may not seem a very startling proposition. I believe, however, that all professions are so thoroughly conservative that they would hardly ever budge an inch if not impelled by controlling influences outside.

Now, let us examine the hollowness of our whole system of consultations. A patient under the care of a general practitioner drops into the rooms of a consulting doctor, sometimes with a verbal message or a short letter, and as often without either. He undergoes an examination which, under the circumstances, may be very imperfect, receives verbal advice, and very often an opinion so ambiguous, so undecided, as to be practically valueless. Hurried examinations, an endeavour on the part of consultants to do more than they legitimately can, lead to the cultivation of a talent in too much repute—that of concealing all doubts and difficulties, and of giving opinions which in any event will turn out quite correct. Of this course I would even dispute the worldly wisdom. I affirm without hesitation that if we are to have medicine and surgery raised more and more to the dignity of a science, and the profession advanced in worldly estimation, we should aim at having more precise knowledge, more early and

accurate diagnosis, and more certain prognosis and treatment. This can only be secured by an expenditure of time, by giving to each individual case the most painstaking examination. I do not conceal from myself the complex questions which may render a clear opinion almost out of the question, but this only demonstrates the imperfection of our knowledge and the hopelessness of advancing medicine and surgery, which have already attained such vast dimensions, by the labours of men who pretend to an “all-round” capacity. We require concentrated, not diffuse, light to dispel the mists. We must look for the attainment of truly scientific knowledge to the labours of educated physicians and surgeons who, wisely reckoning the slowness of human progress and the shortness of the span of man’s active life, fix their attention mainly on limited departments, explore fields shrouded with darkness, endeavour to add new territory to the domains of knowledge, and utilise all previous discoveries to guide them on their chosen paths of research. Practically almost all our advances have been made by men who have so concentrated their efforts.

I now intend to suggest a mode of consultation which would, I submit, improve greatly the status of the general practitioner, and raise a class of consulting practitioners of special eminence. Let us take a lesson from the legal profession. A man of means, if touched in pocket or in feeling, consults his solicitor, requires a case to be stated for counsel, a fee to be marked according to the difficulties of the case and the standing of counsel. Money is very often no object, and this even in cases involving a mere trifle or arising from offended vanity. Yet, in matters of health and life we have no trouble taken, often not even a letter from the attending doctor; the consultant receives his one, two, or five guineas, as the case may be, for work which, if thoroughly done, would require the examination of almost every organ of the body, complex urinary tests, frequent microscopic examinations, the use of the stethoscope, laryngoscope, ophthalmoscope, sphygmograph, or hæmatocytometer. How many men, in large practice, for any ordinary fee, could be expected to do this work, and how many men are capable? I fear not one but several physicians and surgeons of eminence in special departments would be required to give reports on these questions. Is it to be supposed that a man of ample wealth would hesitate for a moment in a matter of such extreme importance as a question involving his own life to pay liberally for a complete statement of his case by his family attendant, and suitable fees to consultants for a full opinion on every point? We have too little formality in the profession. We are got at much too easily. To carry out such a system as this—and of course it would be applicable only to persons of considerable means—the men in general practice would require more leisure, and the consultants would be obliged to limit very much their consultations both in number

and scope. Then look at the incentives to care on the part of every member of the profession. The doctor who wrote the case would find his credit involved, and would not, therefore, spare any trouble to show himself conversant with all the bearings of the malady; professional men would be very careful about the preparation of documents which might be kept for future reference amongst the papers of their patients. The consultant would be obliged to be equally careful, as in case of an unfavourable opinion he would perhaps be subjected to the judgment of men more able or more careful than himself. This is precisely what happens from day to day in the profession of the law. In case a barrister gives an opinion which is not so clear as to satisfy the solicitor or his client, the same case is sent to one or more counsel for further advice, and the opinions compared. How much better this than the utterly unsatisfactory, haphazard system which has prevailed up to the present time in medicine. I need not point out to you that the adoption of such a system would lead to the cultivation of special branches by consultants to an extent hitherto unknown.

I need not say that I have been a careful observer of a tone of speech which has been cultivated in many quarters, and which is based on false notions of human capabilities, and of what is best for the interests of the public and of the profession. We have heard of the “all-round” man; but, if you allow me to say so, I think the pretension by any man to be what has been called the “all-round” man, bears with it the evidence of rather too much self-satisfaction. I should like to see the man whose opinion in every branch of medicine and surgery, or even medicine or surgery, would be accepted by the educated public with any confidence. Consultants, no matter how great their attainments, or how wide their education, come to be specialised, not simply by their own natural taste and peculiar capacity, but by the discernment of the public, and the very action of the profession itself. In case of ovarian or uterine tumours in wealthy patients, do you not select Spencer Wells or Keith; and are not these gentlemen, through your very recommendations, and by the influx of patients suffering from special ailments, obliged to become special practitioners, their whole life-work being specialised? In obscure nervous affections do you not consult Brown-Sequard, Charcot, or Hughlings Jackson? I might go over the whole range of medicine and surgery in illustration of the tendency of the profession to move towards specialism, at least as regards consultants and operating surgeons. I anticipate, too, that our future advances will be by special practitioners—in fact, all our progress for a great number of years has, as I have already said in another way, resulted from a concentration of talent on some particular department of medicine or surgery by men of good general knowledge, who have directed their energies in a particular groove.

I can only say for myself that, in my opinion, the questions to be solved in connexion with even one of the departments in which I chance to be actively engaged might occupy, with advantage, the whole lives of many able men—I allude to the department of the ear. No doubt a vast deal has been done in recent years, and the results of the most brilliant character are commonly obtained; but still there are problems, most important problems, waiting solution. I ask what man engaged in the multifarious duties of general practice can afford to give his time for that patient observation, that close study of the individual cases which are essential to make a single step in this difficult department? To a man engaged in the hurry-scurry of general practice from morning till night and night till morning, the thing is wholly impracticable; and if we are to wait for the advance of knowledge of ear-disease for some universal genius, we shall wait, I fear, till the “crack of doom.”

But not only is the tendency to a specialisation of consultants, but there is a steady advance towards more or less of specialism generally. There is a spread of knowledge amongst the general community which will precipitate the change. Families, instead of having one doctor, will soon have several. There will be some re-arrangement; but it will be a positive advantage both to the public and the profession. I have no doubt that it will be soon quite common for families to consult independently and directly the doctor they consider best qualified to give effective aid in any particular ailment, instead of consulting really or formally one for everything. The gynæcologist would have charge of midwifery and diseases of women; the ophthalmic and aural surgeon, of cases of disease of the eye and ear; the general surgeon, of general surgical ailment; and the physician, of the ordinary medical cases. I trust that I have been as plain as I intended to be. I have, no doubt, touched on many knotty points, and I may have run counter to some pet professional notions. At the same time, I would have you bear in mind that, in all human affairs, diversity of opinion and honest but conciliatory maintenance of a position believed to be right, is the best safeguard against that absolute stagnation which is alike the ruin of states and professions.

Dr. Whitla proposed and Dr. John Moore seconded the nomination of Dr. Barron.

Doctor Esler handed in the following notice of motion “That after the present year, the journals now received by the society be discontinued and the state of the library discussed, with the object of making it more useful to the members”

Professor Dill moved and Dr. John Moore seconded that the day for the Annual Dinner be fixed for the 7th December, the day of the meeting of the N. I. Branch of the British Medical Association at 7 p.m. Passed unanimously.

It was decided to have two charges, one for the dinner and one for the wines; and it was agreed to have the dinner at Thompson’s unless the room be unsuitable. The President, Dr. Dill and Browne and Wheeler to act as a dinner committee.

William A. McKeown

Second Meeting Session 1882–83 November 28th ‘82.

President Dr. McKeown in the chair, present Dr. T. K. Wheeler, Snr., Fagan, Esler, Workman, Kevin, Mackenzie, Core, Wadsworth, J. Smith, Jr., McHarry, and Whitla.

Dr. Barron was unanimously elected a member of the Society.

Dr. Whitla showed a patient the subject of Hodgkin’s disease.

Dr. Esler showed some interesting specimens of malignant deposit in abdominal organs.

Dr. Fagan show a patient upon whom he operated on for Dupuytren’s contracture of the fingers. He also showed a cast of the same before operation.

Dr. Esler introduced the motion of which he gave notice last meeting concerning the Library and the journals.

The following resolution was proposed by Dr. Whitla seconded by Dr. McHarry and passed unanimously

“That a committee consisting of Professor Dill, Drs. Core, Esler, McKeown and Dempsey be appointed to get all available information about the town libraries and to draw up a report suggesting, if possible, some means whereby the Library may be placed on a sound basis”, Dr. Core to be convener.

It was also agreed that a circular be addressed to all members of the Society asking them to return any books they may have belonging to the society.

William A. McKeown

Third meeting session 1882/83 December 19th.

President Dr. McKeown in the chair, present Drs. John Moore, J. W. Browne, Dempsey, Core, McConnell, Workman, Wheeler, and the Honorary Secretary. Barron.

Dr. Workman showed microscopical specimens of a sarcomatous tumour of the eye, and Dr. Browne gave a history of the case from which the eye had been excised.

Dr. Browne showed the kidneys and bladder of a patient whom he operated on for stone; also two stones which he removed. The kidneys were dilated and full of pus, the bladder concentrically hypertrophied and the ureters dilated.

He also showed the kidneys and bladder of a patient who had suffered for a long time from stricture of the urethra. Both kidneys were much enlarged and the right pelvis greatly dilated. A small calculus was

removed from the bladder. An interesting feature of the case was that the patient at one time passed what seemed a cast of the urethra. A section of this showed that it was probably a piece of catheter encrusted with phosphate deposits.

Dr. Workman requested the Society to grant him the use of their Pathological Room in the hospital on Wednesdays and Fridays for holding a histological class. Permission was given him to do so.

R. F. Dill, Chairman

Fourth meeting January 9 1883.

Present, Professor Dill in the chair (in the absence of Dr. McKeown President), Drs. J. W. Browne, Dempsey, Esler, Barron, Wheeler, Jnr., Whitla.

Dr. J. Lindsay (Royal Hospital) was proposed as a member of the Society by Dr. Whitla seconded by Dr. J. W. Browne.

Dr. Dempsey reported on behalf of the Library committee that he had seen the Town Clerk and learnt that no steps could be immediately taken in reference to the Public Library as the question was not sufficiently advanced. The matter was referred back to the Library committee.

Dr. Barron showed an interesting specimen of aneurism of the basilar artery.

Dr. Dill read a paper upon puerperal tetanus.

William A. McKeown

Fifth Meeting January 23rd 1883.

Present, Dr. McKeown in the chair, Drs. Harkin, Wheeler, Snr., McFarland, Esler, Dempsey, Barron, Mackenzie, Kevin, Whitla.

Dr. J. Lindsay was unanimously elected a member of the society.

The Honorary Secretary reported that owing to the difficulty of getting any M.S.S.s from the members, that he would recommend the transactions of this and last year were brought out together. This was agreed to.

Dr. McKeown, President, proposed Dr. St George, Lisburn, and Dr. Wheeler seconded his nomination as a member of the Society.

Dr. Esler gave notice that he would move meeting after next meeting that the periodicals for 1883 be no longer left on the table but be kept by the Librarian.

Dr. McKeown showed two interesting cases of sympathetic ophthalmia.

Dr. Harkin read an interesting paper on the pathology and treatment of infantile diarrhoea.

Paper:¹ *The subject of infant mortality, to which diarrhoea is a prime contributor, is not alone of scientific interest, but of national concern. Communities do not increase so much by a preponderance of births as by a diminished death-rate, and to compass this desir-*

able result should be the end and aim of all our sanitary arrangements. Whenever on the evidence of reliable vital statistics we are assured that an exceptionally high rate of mortality prevails at any period of life, at a special season of the year, or in any particular locality, we may reasonably conclude that the laws of health have been disregarded, and that the local controlling influences and surroundings are in an unsound condition.

So long indeed as we must admit with Dr. West that one-half of the children born in these kingdoms perish before attaining their fifth year, or with Sir James Simpson that every fourth or fifth grave is dug for a child under twelve months, we must also own that our social and sanitary customs are defective, and our boasted progress in science and civilisation is without foundation in fact. We have a striking corroboration of these statements, and an indisputable proof of the awful waste of infant life in this country, in the returns of the Registrar-General for England, who tells us that of four millions of deaths registered in England and Wales in one decade (1851 to 1860), nearly two millions were of children under five years of age. The greatest number of deaths occurs in the first year of the quinquennial period, and is chiefly attributable to the influence of diarrhoea—for fatal diarrhoea is essentially a disease of infancy; that it should be so affords matter for most serious consideration. We are the more impelled to the study of this problem by the knowledge that although during the course of the present century great progress has been effected in the reduction of infant mortality from all causes under the first five years—viz., from 70 to 27 or 28 in the 100, and also that during the summers of the early part of this century official returns assure us there was a comparatively small mortality from infantile diarrhoea, yet in recent years the deaths from this disorder have exhibited a marked increase. Moreover, the deaths from diarrhoea under one year, as compared with the deaths at all ages in England and Wales from the same cause, have steadily increased—i.e., from 44 per cent, in 1847 to 64 per cent, in 1873 (British Medical Journal, Nov., 1875).

What causes this increase, with the concurrent decline in the death-rate of typhus and typhoid fevers, it is difficult to determine; it may possibly be accounted for by the fact that while in the last seventy or eighty years the filth accumulations of our large towns have been reduced by the abolition of cesspools, this result has been attained at the expense of the purity of our rivers, from which the water supply of large towns is generally derived.

The drainage of smaller communities is poured into the stream nearer its source, and the residents lower down imbibe with the water supply the germs of zymotic disease—the undue proclivity of children to diarrhoea being possibly owing to their greater depen-

¹ [Dublin Journal of Medical Science, 1883, v75, p307.]

dence upon the use of water for milk dilution, &c., the beverage of adults being generally of a more composite nature.

The prevalence and fatality of summer diarrhœa is generally attributed to the influence of high temperature, subject to some qualification, for Dr. Laycock has long since demonstrated that it is only in the absence of a rainfall sufficient to flood the sewers of a large city that the epidemic rises to its full development, and that its decline and subsidence is sure to follow on the occurrence of this event.

In large manufacturing towns, the great centres of industry, whose increase is so rapid that sanitary arrangements are unable to keep pace with them, infantile diarrhœa is always prevalent—in summer as an epidemic, at other seasons in an endemic or sporadic form.

Besides the remote or predisposing cause referred to, the proximate causes of infantile diarrhœa are of a varied nature, chief of which is defective alimentation, the persistence of the colostrum in the mother's milk, foul air, insufficient clothing, prolonged dentition, hepatic derangement, inattention to cleanliness, defective sewerage and impure water, the absence of maternal care while the mother is from home at work, and the nostrums administered to quiet the baby while away from it.

The prevalence of hand-feeding, which is not limited to the poor, but which is practised among the comfortable classes and the votaries of fashion, is also a pregnant source of infantile diarrhœa. Thus, when a mother, whether from caprice or necessity, withdraws the natural nourishment from her child, the substitute supplied is too often suggested by ignorance or prejudice. Among the poor the evils of over-feeding, among the rich from false theory, and sometimes from a less excusable motive, the evils of a diluted milk supply, prevail to the injury of the nursing. "It would seem incredible," says *The Lancet*, "but that daily experience teaches us the fact, that large numbers of persons occupying decent positions in society systematically starve their children in respect of that article of food which is of all the most essential to their nutrition. Even to very young and fast-growing children they give cocoa with water, and not always even a suspicion of milk, corn flour with water just clouded with milk, tea, oatmeal, baked flour, all sorts of materials indeed as vehicles of milk, but so lightly laden with it that the term is a sham. There are thousands of households in which the children are reared upon this miserably defective dietary—pale, slight, unwholesome-looking, as their parents say, 'always delicate'—households, too, in which wine to the value of four or five shillings is every day consumed in the diningroom. In some there is the excuse of ignorance; in many the stint is a simple meanness, a pitiful economy, which is supposed will not be open to the criticism of observant friends."

But while this discreditable statement is too true, I fear that our profession shares the blame, for many of the body are advocates of this principle of dilution, and this, like many other "vulgar errors," owes its origin in recent or remote times to the dicta of the family doctor. A fallacy very prevalent among nursing mothers is that when diarrhœa arises during protracted dentition, any attempt to arrest its progress would prove fatal to the infant, and for this reason, or rather prejudice, many little patients are allowed to get into collapse before medical aid is asked.

A number of varieties of diarrhœa have been described by various nosologists, dependent principally upon the nature of the evacuations, and a plan of treatment recommended for each. As for those with fœculent, bilious, mucous or serous discharges, it is not my intention to follow them in their sub-divisions, but to refer to the general principles upon which, in my opinion, the treatment should be conducted. In its treatment the dictum of Sydenham, which states that "disease is nothing else than an effort of nature struggling by every means to exterminate the morbid matter, and so restore health," is only applicable in the primary stage of the complaint, where it is often judicious to assist nature by a gentle laxative in getting rid of undigested food or other causes of irritation in the intestinal canal, the eliminant treatment cannot wisely be continued much further, nor would the expectant plan of treatment be permissible. The drain should be stopped at all hazards, and our efforts be directed to the speedy extinction of the disease, and the rapid restoration of the infant's health. But in the cure of this disease, perhaps more than in any other in the medical nomenclature, is its average mortality modified by the plan of treatment adopted; nor is there one in which, by following a mischievous routine and the traditions of the nursery, a mild attack may be so speedily converted into a hopeless one, or vice versâ, by scientific treatment, the sufferer be restored rapidly to health. Among the ideas generally received by mothers and nurses, and unfortunately fostered by the approval or tacit permission of many members of the profession, is the indispensable necessity of the free administration of milk to the child in diarrhœa.

This conviction is so strong as to blind otherwise intelligent people to the immediate laxative results of each dose. They argue, when they reason at all, that whereas the use of milk in health tends to costiveness, therefore in disease it must have a similar tendency, and it is most difficult to prevail with them to make the change; and yet in those cases in which a cure was effected under my care it was almost only when complete ab lactation was resorted to, in the case of both nursing and weanling; and where milk was promiscuously ordered by my medical brethren, with otherwise scientific treatment, I have known too many cases ending fatally.

In every case, then, I enjoin total abstinence from milk—the mother's, or the milk of the cow, as the case may be, and order, as a substitute, arrowroot prepared with water, some sugar and port wine being added; and it is wonderful how much wine given in this way an infant of a few months will consume and require; beef-tea, carefully prepared and freed from fat; and, when available, condensed milk, its use being unobjectionable from its being freed from casein, the irritating element in milk. An equally important requirement is absolute rest in the recumbent position, with sufficient warmth to the extremities and surface of the body, counter-irritation over the abdomen by poultices, a sinapism if required, and, failing other remedies, a small blister over the liver, as we have, in almost every instance, congestion of the hepatic system and functional derangement, and tenderness on pressure—this form of counter-irritation will be found most salutary and rapid in giving relief.

As medicine I have long since dispensed with the old chalk mixture and astringent tinctures, having found them in practice too often acting as irritants to the sensitive mucous membrane of the bowels. My chief reliance is placed upon dilute sulphuric acid, either with or without the addition of laudanum in regulated doses.

It is desirable to give it singly in most cases, as it may then be ordered after even loose motions with safety, whereas when combined with opium it can only be administered after express intervals. This remedy cannot be used, however, with the necessary freedom while the ordinary practice of milk-feeding prevails, as it is almost certain to induce colicky pains by the separation of the curd in an indigestible form, and thus increase the sufferings of the infant.

The indiscriminate administration of milk in diarrhœa produces a result almost analogous. Under ordinary circumstances, when a child imbibes a quantity of milk an immediate change takes place in the stomach—the separation and rapid absorption of the soluble particles, water, oil, and sugar, and the formation of the curd, which is again dissolved by the action of the gastric juice.

But in this case the digestive powers of the stomach are much diminished, and portions of the curd pass unchanged into the intestinal canal, ordinarily producing irritation, griping, and purging, and becoming still more acrid when coming in contact with the acid intestinal secretions always present in diarrhœa. In the chronic mucous diarrhœa and in the diarrhœa of measles I have found great benefit from the administration of chlorate of potassium both by the mouth and by enema.

The treatment of choleraic diarrhœa, as it acknowledges a different pathology, is naturally distinct, being of the same class as cholera infantum, English cholera, and epidemic cholera, which, according to all reliable

authorities, differ but in degree, while similar in nature. They are diseases which affect the whole system, and our best guides in treatment are those who have been most successful in the country where it has its constant habitat.

Dr. Hall, who has seen a large amount of cholera in India, proposed to the Royal Medical and Chirurgical Society in London, on October 13, 1874, a plan of treatment which received the approval of the Society, as well as that of Sir Joseph Fayrer, an experienced Indian medical officer. He recommends dilute sulphuric acid, plenty of cold water in the early stage of cholera, and if they fail to arrest the disease, and the patient get into collapse, then the hypodermic injection of hydrate of chloral diluted with ten parts of water, ten grains at a dose. This, he states, has succeeded in the majority of cases. His statement is confirmed by a large number of Indian medical officers, and his theory is as follows:—

The symptoms of collapse he explains by the result of the experiments of Claude Bernard, who taught that they were due to great irritation and hypertrophy of the sympathetic nervous system. Kolman, too, has demonstrated that the right pneumogastric nerve supplies the whole of the small intestines. This is an inhibitory nerve; and Moreau and Lauder Brunton have shown that the division of all the nerves going to a portion of intestine is followed by the secretion of a fluid just like the rice-water stools of cholera. May not, he continues, the stimulation of the inhibitory vagus be followed by results much the same as if the sympathetic supplying the small intestines were paralysed? At any rate the result is thus given by Mr. Higginson:—Chloral hydrate, being a powerful sedative, soothes the irritated nerves, and so relaxes the contracted vessels; the blood is once more uniformly distributed, the pulse reappears at the wrist, the cramps and burning abdominal pains subside, sleep is induced, respiration becomes regular, discharges lessen, the face fills up, the voice becomes stronger, and the natural secretions are restored. While this plan commends itself to our adoption, I cannot recommend it from personal experience, but I may state that I have repeatedly tested the effect of remedies to the region of the vagus in the neck in cases of dangerous and profuse vomiting in gastritis and bilious attacks, with the most satisfactory results, in the absence of any medication of an ordinary nature.

William Aickin M.D.

Sixth Meeting was held upon Tuesday 20th February 1883.

President Dr. Aickin (Vice-President) in the chair, Dr. Wheeler, Snr., Dr. John Moore, Wales, Fagan, Esler, Dempsey, Wadsworth, Mackenzie, Kevin, Lindsay, Whitla.

Dr. Saint George was unanimously elected member of the Society.

Ulster Medical Society
Session 1882–1883
President William Alexander McKeown

Dr. Whitla showed some specimens of tubercle bacillus.

Dr. Fagan showed a living patient who had suffered from fracture of the pelvis. He also showed a specimen of ruptured urethra from a patient who died from fracture of the pelvis.

Dr. Esler read case in which abortion followed tapping for rapidly increasing effusion of fluid in the abdomen.

William A. McKeown

Seventh Meeting Tuesday March 20th '83.

Present, Dr. McKeown in the chair, Professor Dill, Drs. Nelson, Anderson, Gilmore and Whitla, Dempsey.

Dr. McKeown, President, exhibited a patient upon whom he had operated for a large polypus of the ear which had grown from the middle chamber and penetrated the tympanum. The large perforation left after the removal of the tumour had almost entirely disappeared.

Dr. Anderson read an able paper upon the arrangement of the peritoneum in mammals and in man. He also read notes of various cases of anatomical anomalies.

Dr. Esler's motion was not considered in his absence.

R. F. Dill M.D. Chairman
April 4th '83

Eighth Meeting of the Society was held upon Tuesday 3rd April 1883.

Present, Professor Dill M.D. in the chair, Drs. Wales, Anderson, Lindsay, Wadsworth, Anderson, Mackenzie, Whitla

Dr. Wadsworth showed an interesting case of scleroderma in a male adult.

Dr. Lindsay read a paper upon a case of purpura.

William A. McKeown

Ninth Meeting of the Society was held upon Tuesday 16th April '83.

Present, the President (Dr. W. A. McKeown) in the chair, Professor Dill, Dr. J. W. Browne, Dr. Aicken, Dr. Anderson, Dr. J. C. Smyth, Dr. Dempsey, Dr. John Moore.

Dr. McKeown (President) exhibited a patient suffering from dislocation of the lens into the vitreous in both eyes. He had removed the lens from the left eye by an incision at the lower part of the cornea.

The President also exhibited a portion of bone removed from the posterior part of the right ear which was considered to be the mastoid process of the right temporal bone.

Professor Dill gave a very interesting and instructive discussion of displacement of the uterus.

R. F. Dill, Chairman
29th May 1883

The Tenth Meeting of the Society was held upon Tuesday 9th inst May 1883.

Present, Dr. W. A. McKeown President in the chair, Drs. Dill, St. George, Dempsey, McConnell, Lindsay, Fagan, Barron, Byers, Esler, Browne, Whitla. Dr. Sinclair was present as a visitor.

Dr. Lindsay showed an interesting case of lateral sclerosis in a child. Dr. Lindsay then read a paper upon lateral sclerosis.

Dr. Byers showed a paraplegic patient in whom various reflex phenomenon were well marked.

Dr. Fagan showed a glandular tumour removed from the floor of the mouth.

Dr. Barron showed for Mr. Fagan, who had to leave the meeting, a specimen of diseased knee joint.

Dr. Whitla proposed and Dr. Dill seconded the nomination of Dr. Sinclair, Wellington Park.

J. Moore
17th July 1883

Annual Meeting July 17th 1883.

Present, Dr. John Moore in the chair, Drs. J. W. Browne, Wadsworth, Dempsey, Esler, Barron, Smith (Carlisle Circus), Mackenzie, Wheeler, Snr., Wheeler, Jnr., and Whitla.

The Secretary read report of Council and Dr. Esler made a financial statement; both reports were unanimously carried. The Honorary Secretary, Dr. Whitla, resigned office and Dr. McKenzie was unanimously elected in his stead. Dr. Esler was unanimously elected Treasurer.

Professor Dill on the motion of Dr. Whitla seconded by Dr. Wheeler, Snr., was unanimously elected President.

Dr. Whitla and Dr. McConnell were elected Vice-Presidents. Drs. Dempsey and Barron were elected Honorary Librarians.

Dr. Workman was elected Pathological Secretary.

The following Council was elected: J. W. Browne (10), Charles Wadsworth (9), R. Clement (6), J. C. Smyth (5), John Fagan (5), John Moore (4).

Drs. Wheeler and Barron were appointed Auditors.

Dr. Dempsey moved and Dr. J. C. Smyth seconded and it was unanimously agreed that the Treasurer be directed to invest £50 in 3 percent consols.

Dr. Dempsey give notice that at next meeting he would move "That the reception of the different medical journals of the Society be discontinued at the end of the present year owing to the unsatisfactory condition of the Library".

Dr. Sinclair was unanimously elected member of the Society.

William A. McKeown
November 27th 1883

ULSTER MEDICAL SOCIETY

SESSION 1883–84

The First Meeting of the Society was held upon Tuesday 27th November.

Present, Professor Dill President in the chair, Drs. McKeown, Harkin, Whitla, Esler, McConnell, Dempsey, J. W. Browne, John Moore, Barron, Lindsay, J. C. Smyth, McKenzie Secretary. Dr. McKee was present as a visitor.

The President briefly thanked the members of the Society for the honour conferred upon him by again electing him president of the Society.

The President then proceeded to deliver his most eloquent and interesting address.

Paper:¹ GENTLEMEN, I have to thank you, which I do sincerely, for this renewed expression of your confidence, in electing me so soon again to the Chair as President of "The Ulster Medical Society."

It is rather a peculiar coincidence that, on the former occasion when you were so good as to confer upon me a similar honour, it happened to be on the fiftieth year from the time I had entered upon my medical studies; now it is the fiftieth year since the time at which I became legally qualified to occupy any professional position; but I did not then, nor for some time afterwards, sever my connexion with the University. The fiftieth year has been by certain persons and under certain circumstances called their jubilee year, because, I presume, it was the name given to certain joyous celebrations associated with a release which they had experienced. Be this as it may, or whether there is any analogy between the circumstances in which I stand and those in which those persons stood, I need not here stop to inquire; but, this I know, I have not yet sold my inheritance, neither have I felt my position to be a bondage, and I am not, I assure you, at all anxious to be released from it. Nevertheless, I hope you will allow me the privilege of calling this my jubilee year, because of the many friends I have and whom I see around me, and because of the health and the heart I possess to appreciate their earlier and their later favours, and because I can now look back upon half a century of professional life, with its many varied and its chequered incidents, occurring over that lengthened period and appearing in all the tints of lights and shadows, and yet with all the fresh and fondly-cherished memories of the past.

My first recollection of University life is of what was called "The Blackstone Examinations" in Glasgow, that being the name given to matriculation in that ancient University because of the Blackstone Chair, upon

which the student is seated when undergoing his entrance examinations; and I had occupied it immediately before Archibald Tait, the future Archbishop of Canterbury. At these examinations Archibald Tait scored such high marks that he afterwards obtained the Foundation Scholarship, which eventually carried him up to the Oxford University, and I have always watched with the greatest interest his steady progress and his brilliant career from these Blackstone Examinations, before Sir D. K. Sandford, the accomplished Professor of Greek, until elevated to the Archbishopric of Canterbury, the highest episcopal chair in the empire; and I fancy I can still hear his clear, distinct, and measured readings of those old pentameters and hexameters; and his readings of passages from Sophocles and Euripides were all but equal to an Athenian dramatist.

My second recollection is again incidentally associated with another great name, but of a different order and under different circumstances. The day after I had passed my examination in the Royal College of Surgeons, London, being disengaged for a short time, Dr. Southwood Smith, the popular physiologist of that day, asked me to give him some assistance in dissecting and in making a dried preparation of the body of no less a person than that most celebrated and able political economist—viz., Jeremy Bentham, and yet with all his acknowledged greatness, I could not, I assure you, discover the slightest difference in the dissections of his body from those which were taken from the paupers' burying-ground, Bully's Acre, Dublin. But I did discover a marked difference between it and that which he considered as his Great Grand-father the Oyster.

My third recollection, though not associated with any of the great ones of earth or water, is not on that account of less moment to myself. It was the day after I had been appointed a Dispensary Officer to a district, situated in as beautiful and picturesque a little neighbourhood as could be found in all Ireland again; and the women were as lovely as the scenery was charming—a land flowing with the milk of human kindness and the true sweets of social enjoyment. I remember well that bright May morning riding down that village street, on my way to visit a dispensary patient far into the country, and receiving the congratulations and the salutations, and the smiles from every person, in every door and from every window as I passed along; and I could scarcely suppress the feeling that my fame and my fortune were within "measurable distance."

After reaching the patient's house, examining and prescribing for one whom I found far advanced in consumption, and to whom I could hold out but little hope of relief, and less of recovery, I left saddened at the thought of being able to do so little for that young and anxious seeker after life, but had not gone far when I was stopped and asked (as was the custom to waylay a medical man on his professional rounds) to pay a visit at a very comfortable-looking neighbouring farmhouse.

¹ [Dublin Journal of Medical Science, 1884, v77, p174.]

At the door I met and was asked by the farmer's wife, who stated that she wished me to take a little blood from her daughter's arm, as was her habit at that season of the year, and, as was then our habit, without asking any impertinent professional questions. And although a fine strong and healthy-looking country girl, I pulled out my lancet, most pedantically, tied up her arm and bled her freely and to syncope; she was soon placed in the recumbent position, and the arm immediately adjusted by means of a pad and bandage. When at the door and leaving, the good wife put into my hand a nicely-rolled up little bit of paper, which I graciously accepted; and as I dare not open it in her presence, I mounted and got as quickly as possible round to the other side of the hill. When well out of sight and with patience all but exhausted, with anxiety to realise my first professional fee, I pulled up, unfolded the little bit of paper, and exposed to view my first honorarium, which amounted to—what do you suppose?—just one silver sixpence!

I sighed—but again I thought it might be quite enough for what good was done. However, I rode home an humbler and not a much richer man, and I have often thought since that, let the fame go as it may, from that day till the present the fortune has appeared as a dissolving view; and that, had the blood been less and money more, the balance of power might have been better preserved.

You will not be surprised when I say that I have had some difficulty in determining upon the choice of a subject suited to a scientific and a critical audience; and I have felt that the more because of the numberless addresses to which we have been treated of late. But I feel much relieved because of the valedictory address with which we have been favoured by our out-going President. But however able most of these addresses are proved to be, yet there are to be found in some of them scientific fallacy, in others philosophical fiction, and in not a few you may travel over a great breadth before you come upon a useful fact, or a single grain of truth. Nevertheless, what I have to offer to-night must appear beside them as of little importance, and be looked upon as very small fry; so that I feel I am in the somewhat awkward position of the punctiliously polite Greek gentleman who, while performing the funeral functions of an infant daughter, felt called upon to make his excuses to the spectators for bringing out such a ridiculously small corpse to so large a crowd. But though small and insignificant what I have to offer, I hope you will find it to possess a little more vitality than the Greek gentleman's child; though for size and appearance (our late President and recognised oculist will set me right if I am wrong) much depends upon the medium through which it may be viewed—through one medium it may be very like a whale, through another it appears as a little fish; but no matter if viewed through the spectacles of a Bishop Berkeley.

I hope it may not be considered here out of place if I occupy a few minutes upon some points of interest associated with Medical Education as we now find it, and compare these matters with what we know of the state of education in former times, and, observing the results, draw our conclusions.

Professor Huxley, lecturing the other day, made use of this statement—viz, “that when one of his sons was commencing his medical career he was perfectly astonished when he compared the course of instruction, the requirements, and the kind of examinations which were needed from him, with the very small and perfunctory necessities of his own time.” If the course of instruction, requirements, and the examinations are in his own opinion the sine quâ non of an educated profession, then I submit that this statement of Professor Huxley is rather an unhappy one as coming from him, for with the small and perfunctory necessities of his time, what shall we say or think of his acquirements or of the rank he holds among the learned and scientific men at present. And Professor Huxley is no exception, for although it has been stated that the difference between the past and the present is that the former was the age of literature, the present the age for science; yet I think I am in a position to prove that while there was more profound learning, I believe there were also not a few of the most important scientific discoveries made known, so that education altogether stood as high as we, with all the boasted progress of the present day, do yet enjoy; and the son, I feel persuaded, shall have trouble in rising to the level of the sire; that the men of other days possessed a learning and attainments which many of the present day would pale before.

Medical Education is, I believe, at present passing through a severe crisis—it is passing through very troubled waters. For, have there not of late been too many as well as extravagant changes made in some of our Universities, and too many attempts at medical legislation, and I confess that I, for one, was not sorry that the Medical Bill before the House in the last session did not pass into law. And I know that our students are very much hampered and harassed by these capricious changes as well as by the number and eccentric character of the examinations which they have now to undergo, because of which they are obliged to devote themselves to the advanced departments of science to the neglect of more useful, because more practical knowledge.

I would venture to offer an opinion upon another matter of some interest to us in the present day. I believe it was one of the errors of the age to open our colleges, our schools of medicine, and our universities to women, thereby enabling them to compete with our young men while pursuing their medical studies, and in obtaining degrees and other medical distinctions.

Indeed I should have hoped that the culture and refinement of the age would have forbidden such a con-

summation, as that the two sexes should be found receiving united medical education. Which of us would like to see his sister, his daughter, or other young female friend, in the dissecting room, and at work in common with the youths of the opposite sex. Which of us would willingly join in consultation in certain cases with Dr. Elizabeth—, or be found investigating certain diseases with Dr. Mary—. I believe the properly constituted mind of either sex would revolt at the very thought of such a practice.

But apart from what some would consider the sentimentalism of the subject, woman, from her constitution and her habits, is altogether incapacitated from taking part in the toils, the labours, the responsibilities, the anxieties necessarily associated with medical professional life. When we consider her habits, her functional arrangements, her capricious tendencies, her domestic associations, her bodily weakness if you will, then say is she fit to take upon herself all that is necessary in the work of the profession, both by day and by night. And I believe she is disabled even more by reason of her mental constitution than from her bodily characteristics, which I shall endeavour to show you. It is unnecessary, though, for me here to attempt to prove that it is the brain matter which possesses the power of evolving mind, and which places the beings possessed of this power in the highest rank of creation; but it is necessary, before determining finally the question under consideration, to ascertain what are the essential points of difference between the mind-producing organ of man and that of woman. It is a well-recognised fact that the brain of man is larger than that of woman, the average of the one being forty-nine ounces and that of the other forty-three ounces—the difference in favour of the male brain being six ounces. It is also an accepted fact that the size and weight of an individual's brain are in direct relation to mental capacity; and it is a remarkable fact that whilst in men of high intellectual development, as in Cuvier, the brain has been found to weigh sixty-four ounces, woman's brain has never reached that weight by eleven ounces. We also find that the female brain is not only smaller than that of man, but it is different in structure and in shape, which I would say counts more as regards mental faculties even than does the element of size. Thus we find that the frontal lobes in man are larger than those of woman, and the depth of the convolutions and the density of the cortical or grey substance are greater. The inevitable conclusion we must arrive at is, that as man possesses more brain than woman, he must of necessity possess more mind. But there is not only a difference in quantity, there is also a difference in quality, as in shape and structure, so there must also of necessity be a difference of function; and from this fact I am disposed to argue that the emotional is the first characteristic of a woman's nature, and which holds its ascendancy over her intellectual qualities; and that, no

matter how highly she may be educated, inasmuch as the brain matter is not there either in quantity or in quality, she is incapable of a sustained, an original, an intense degree of thought. But while man's intellectual nature is his chief, his supreme characteristic, and by which he originates, he designs, he discovers, he explores—he, in fact, all but creates, yet who will venture to say that the brain from which will flow a wife's fidelity, a mother's affection, a sister's devotion, and a woman's gentleness, does not mark her out as one who shall rise higher in the scale of a moral and a spiritual life, than the brain from which flows the dry interpretations of the laws of nature.

If it were necessary to pursue this line of argument further, I might show that it is impossible for us, properly, to continue to entertain the novel idea of women occupying the field of medicine, because, if for no other reason, of the excessive strain upon her physical and her mental powers by which permanent injury to both mind and body is often found to follow, and this every physician of experience knows to be the case. I might also show that as woman's brain becomes developed at an earlier age than that of man, it is unfair to place them in competition at this time of life. I assert all this even in face of the statement which I see made at a public meeting and reported the other day—viz., “that women were gradually coming to the front.” In the presence of such advocates and with such advocacy I only wonder that they do not come careering to the front at a gallop. But I am persuaded that this movement must soon come to an end, and that when the novelty, excitement, and sensationalism shall have passed away, this phantom caricature will collapse, and woman will return to her normal sphere.

May I occupy your time a few minutes longer, while I shall endeavour to establish the proposition which I have made in favour of the learning, the attainments of the men of former time. To say that the works of Hippocrates, and Celsus, and Galen, are accepted as amongst our ancient medical classics would be but expressing a truism, as they are to be found in the libraries of our Colleges and Universities. And I do not say more of the earlier Arabian authors, as Razes, Avicenna, Albucasis, than that their works still live and exert a power amongst us. If we consult some of the works of the 13th and the 14th centuries, we shall find that at these early periods, Leonicensus demonstrated that difficult problem which then existed—viz., that of making a correct diagnosis of syphilis, which had been up to that period confounded with leprosy. The treatment of syphilis, however, remained for a short time an unsettled question, as Leonicensus rejected mercury because of so many persons dying from its effects. And amongst these Cardinal of Segorbe, Alonso, &c., whose deaths naturally prejudiced the public mind against this drug; soon, however, it was made manifest by Torello and Theodoric that mercurial unction was the

true remedy (in fact, it was proved to be a specific for this terrible disease, as then experienced) by keeping up the “flux,” as it was called, for three weeks.

And it is to our minds rather an amusing incident to find that such questions in that day were made the subjects of poetry, and that one Fracastorius, in Pope Leo’s time, wrote what was considered an admirable poem, entitled “Syphilis,” in which the chancre, the bubo, the ulcerated throat, the hoarse voice, the mercurial unction, fumigations of cinnabar, the flux, or rivers flowing from the mouth, are set forth and poetically recorded. Whether this poem is to be accepted as sacred or profane poetry you are the judges.

There are other instances, at an early period in the history of medicine, of correct diagnostic powers and successful treatment of disease. Sea-scurvy, which appeared in a most violent form at first, was soon understood and mastered by its true remedy—viz., fruits and vegetable diet.

Mead, in his travels on the Continent, met with the writings of Bonomo, which contained an account of the cutaneous worms which generate the itch. When he returned to London Mead presented an analysis of Bonomo’s researches to the Royal Society, and recommended sulphur as a specific for this very nasty and troublesome disease.

Thus we have in remote times not only a correct diagnosis formed of syphilis but also its specific treatment, in mercury. We find that sea-scurvy was successfully treated with lemon-juice, itch with sulphur, and intermittents by Peruvian bark.

Where, in modern times, do we find anyone who can lay claim to discoveries of more value or of more practical importance than are those I have instanced. But in coming a little further on, where is there to be found, at any period, more scholarly attainments or greater breadth of learning than are enjoyed by Linacre, Letsum, Caius, Sydenham, and Gooch, and a host of others, some of whom Dr. Johnson (no mean authority) pronounces well versed in the writings of antiquity, more particularly in those of the great Roman orator and philosopher, whose luxuriance of style they not only imitated but thoroughly mastered; and we know that the works of these men have not only made their impress upon the age in which they lived, but they have made their mark upon the world’s history.

What, in modern physiology, can at all compare with that grand old discovery, the circulation of the blood; and does not the name of Harvey call up recollections that justly place him in the foremost rank of natural philosophers, and whose services conferred upon anatomy and physiology what Newton rendered to optics and astronomy by his theories of light, and by his discovery of the laws of gravitation.

The name of Hunter cannot be omitted in the “roll call” when genius had become the rank and file of the

age, and when by his great personal labours, and at enormous expense, he designed, completed, and established the Great Windmill-street Anatomical School, and handed down to us his vast treasures, known as the Hunterian Museum, and of which the authorities at the Glasgow University are the trustees and principal custodians. To Hunter also are we not indebted for his great work on the anatomy of the human gravid uterus, which is unrivalled for its splendour and the correctness of its delineations.

Among the names which ought to be held sacred by the undying gratitude of mankind is that of Edward Jenner, who should stand preeminent among discoverers, for it would be impossible to find his equal as a benefactor of the human family by his discovery and the introduction of vaccination, which has proved itself a safeguard—a specific against the ravages of a disease worse than the plague.

And as we travel down the highway of medical science we reach another great landmark, clearly defined, and explicitly directing us on our journey. For has not Laennec put into our hands that most valuable and useful instrument, the stethoscope, which might be suitably termed the key of knowledge, by which we can unlock and lay bare some of the most hidden maladies, and by which are opened up to us mines of diagnostic wealth?

These are old truths which bear to be repeated, and the names of those men who brought them to light, and into use, have a claim upon our gratitude, our sincerest admiration, and our warmest acknowledgments.

I have a lively recollection of many successors to those great men, who taught and practised, and who flourished in the early part of the present century. I have only to mention Sir Charles Bell, whose name is so intimately associated with one of the grandest and most important discoveries in connexion with the nervous system.

I might also make mention of the names of Abernethy, Brody, Lawrence, and Astley Cooper. But to come a little farther down, and nearer home, I would mention Colles, and Carmichael, and Cusack, and Corrigan, but especially Graves, who was one of the most accomplished and distinguished physicians and fascinating lecturers that ever appeared in the wards and lecture hall of Sir P. Dun’s Hospital.

But words do fail me when I attempt to speak of that much-to-be-esteemed and long-to-be-remembered William Stokes, who in the Meath Hospital won not only the confidence and affection of his patients, but also the respect, admiration, and love of his students, by his winning presence, his untiring zeal, but, above all, by his unrivalled powers as a clinical teacher; and from the city of Dublin, which had become the scene of his distinction, and in which he exerted a magnetic influence, he sent forth admiring pupils to all parts of the world, and he really enriched and benefited, by the halo

Ulster Medical Society
Session 1883–1884
President Robert Foster Dill

which he flung around, the medical school during his brilliant career.

I have heard him relate, in glowing terms, how (in company with our old friend Creery Ferguson and a relation of my own) he mastered the use of the stethoscope under the eye and the teaching of Laennec himself; and William Stokes was the first physician who introduced and who taught the use of this instrument in these countries. These are assuredly the fathers of medical science, whose names and whose deeds have been bequeathed to us as a rich inheritance, and upon whose ashes we shall never allow a foot to trample scornfully. For, although it was not theirs (nor has become the lot of any yet) to crown or complete the great temple of medical science, yet it was theirs, amidst darker times and amidst rougher and harder work, to dig deep, and “well and truly lay” the foundation and not a few chief corner-stones of this great structure.

Talk of titles, talk of decorations, talk of even peerages, for such men as these. You may confer upon them all the honours that a cold, contemptuous, and effete Government can bestow; you may cover them with stars and garters and ribbons—you may; but the stars shall become dim and the garters and the ribbons fade away, yet the names of these princes amongst men shall never be forgotten; their deeds shall form a bright page in the world’s history, and their memories preserved, because embalmed in undying remembrances—for there is no death, no night there; or, as is so exquisitely expressed by our own Immortal Bard—

You may break, you may ruin
The vase if you will,
But the scent of the roses
Will hang round it still!

Dr. John Moore proposed and Dr. McKeown seconded a vote of thanks to Professor Dill for his most admirable and beautiful address.

The President acknowledged the vote of thanks.

Dr. John Moore proposed and Dr. Harkin seconded motion to the effect that the “Secretary be instructed to write a letter of condolence to the widow of the late Dr. James Moore who was so long a member of the Society”.

Drs. O’Connell and Dwyer were proposed by Dr. Harkin seconded by Dr. Dempsey as members of the Society.

Dr. Smith (Shankill Road) was proposed by the Secretary and seconded by Dr. Lindsay.

R. F. Dill, Chairman
18th December 1883

Session 1883–4. The Second Meeting of the Society was held upon Tuesday evening 11th December.

Present, Professor Dill President in the chair, Drs. Esler, O’Neill, Dempsey, Whitla, Wadsworth, Lindsay and McKenzie, Secretary.

Drs. O’Connell, Dwyer and Smith (Shankill Road) were unanimously elected members of the Society.

Dr. Dempsey brought forward the motion of which notice had been given concerning a discontinuance of the medical monthly and weekly journals after this present year. Dr. Esler seconded and Dr. Whitla supported the motion which was passed unanimously.

Dr. Whitla showed sample of “chyle” recovered from the abdomen of boy 13 years old; 13 pints were removed. Dr. Whitla promised to show the patient, if possible, and give the history of the case at a future meeting.

Dr. Lindsay read a most interesting and important paper on the climatic treatment of phthisis.

Paper:¹ My only excuse for bringing so hackneyed a subject under notice is the fact that I have had a more extensive personal acquaintance with foreign sanatoria for phthisis than falls to the common lot. Circumstances have enabled me to travel widely, and amongst other places I have visited Southern France, Switzerland, Italy, Algeria, Cape Colony, Australia, New Zealand, and California—thus including all the most famous health-stations, with the exception of Egypt.

I am far from wishing to exaggerate the importance of the observations and experience of a single traveller, but I feel confident that some practical acquaintance with foreign lands is a very great advantage in selecting a suitable climate for any given case of disease. At the lowest estimate it clears one’s mind of numerous misapprehensions, makes one doubly receptive of genuine information, and enables the traveller to make due deductions from the roseate accounts so often furnished by interested persons. Only personal experience can thoroughly inform us on many points of secondary but still genuine importance regarding any locality—points, I mean, quite apart from considerations of climate. I refer to such questions as the facilities and expenses of travel, the hotel accommodation, the objects of interest to be met with, &c.—points of prime moment to many invalids.

Though the climatic treatment of phthisis has long enjoyed a wide popularity and an acknowledged efficacy, we are still by no means clear regarding the precise conditions of climate which are generally desirable. We know that certain climates are efficacious, but we are not quite certain on what that efficacy depends. The idea that the dryness of a climate is the essential feature is evidently an error, as cases of phthisis do almost equally well in the intensely dry climate of Upper Egypt, and in the intensely moist and humid atmosphere which prevails at sea. Nor can the degree of heat or cold of any climate be looked upon as the really important point, for phthisical patients flourish in the torrid heat of Australia and amid Alpine snow-fields. Then, again, distance from or proximity to the sea

¹ [Dublin Journal of Medical Science, 1884, v77, p110.]

cannot be reckoned an indispensable factor, as phthisical patients do almost equally well at Algiers and at Cairo, at the littoral towns of the Riviera, and on the Darling Downs of New South Wales. Lastly, elevation above the sea level cannot be reckoned essential, since at present it would be difficult to affirm whether better results are attained at Davos or at Algiers, on the highlands of Colorado or on the sea-coast of California. If, then, neither the temperature of a climate, nor its dryness, nor its elevation above the sea level, nor its distance from the ocean, be essential, it becomes of importance to inquire whether any combination of these features is probably indispensable. Here we begin to see light. So far as I am aware no climate which is both damp and cold has proved useful in the treatment of phthisis. Damp climates succeed in some cases, cold climates in others; but climates which are both damp and cold appear to be uniformly injurious. Secondly, the equability of a climate is probably a point of the most vital importance.

Phthisical patients are peculiarly sensitive to sudden variations of temperature—the most frequent cause of intercurrent attacks of bronchial catarrh and pleurisy which such patients have so much reason to dread. Thus the climates of Algiers, Egypt, and Davos, are remarkably equable, while climates where phthisis is particularly prevalent are usually noted for sudden variations. The purity of the air has been much insisted upon by some authorities, and has even been regarded as the one essential condition. A pure atmosphere is no doubt very important; but I venture to think that no case of phthisis could prosper in any atmosphere, however pure, which was subject to sudden variations of temperature. In formulating anything like fixed principles we must not forget the part which individual idiosyncrasy probably plays, nor another fact more frequently overlooked—viz., that certain climates may furnish the desired change from certain other climates. Thus it is possible, and even probable, that two climates may bear such a correlation to each other that a patient removing from one to the other may thus obtain the exact change, climatic and hygienic, which his case demands.

Before deciding where to send his patient the medical practitioner has first to consider whether the patient is in a fit state to go abroad anywhere. This is often a most anxious and difficult problem, and one of the first importance. There may be noticed at the present day some faint signs of reaction against the practice of sending all phthisical cases indiscriminately abroad, and if this reaction merely tends to greater care and caution in the selection of cases, it will be an unmixed boon; but it would be a great misfortune if any prejudice were to arise against the climatic treatment of phthisis in general. In most cases the choice is practically between that and an expectant treatment which ends only too surely in death. By careful nursing and

wise treatment at home, no doubt, the disease may for a time be kept at bay, but recovery is practically out of the question. It is a cruel thing to send a hopeless case abroad to linger out a miserable end, far from home and friends, amid strange faces and uncongenial surroundings, but it is a much more cruel thing to deprive a patient of even one chance in a hundred by dissuading him from a step on which he is bent, and which is to him full of hope.

In deciding the momentous question of sending a patient abroad, let me say, first of all, that the stage of the malady is not necessarily the first or even the chief consideration. This will sound startling only to those who have given little attention and study to the subject. Some of the most striking recoveries on record have been those of patients in whom the malady had progressed to the stage of cavity before a change of climate was sought, while on the other hand there are many cases only in the first stage whom one would never dream of sending abroad; the high range of temperature, the rapid emaciation, and the feeble attempt on the part of nature at reaction—all showing the utter futility of the step. Not the stage, then, so much as the type of the malady, the family and personal history, the amount of reaction present, and the general constitutional conditions, must be our guide.

There are several cases where the climatic treatment is plainly inadmissible.

1. In acute tuberculosis. Here no treatment is of even temporary avail, and the rapid prostration of the patient makes a resort to travel quite out of the question.

2. During acute exacerbations of the chronic malady. Here the wise treatment is to avoid all causes of excitement and irritation, to soothe the patient, and to wait until the disease shall again resume its chronic character.

3. Where the patient's means are insufficient to enable him to travel with reasonable comfort, or where there is an idiosyncrasy which renders travel peculiarly distasteful and irritating.

The chief difficulty in the decision naturally arises with cases which lie upon the borderland. In an ordinary case of moderate severity, what are the leading indications? A distinguished physician of Belfast once told me that he made it a rule never to allow a phthisical patient to go abroad until the pulse and temperature had been for some time under 100. As a rough and ready rule this dictum has its attractions, and in all probability would be found to work fairly well in practice; but we need some more scientific basis for our opinion. I venture to formulate one or two principles:—

1. Let us ask the question—Has the disease been steadily progressive from the first, or has it shown signs of occasional remittance? Are periods of high pyrexia and severe constitutional disturbance succeeded by periods of comparative recovery, leading us to believe

that the disease in the lung is for a time at least quiescent? These cases which approach the remittent type are, I think, peculiarly favourable for climatic treatment.

2. The milder the constitutional symptoms are in proportion to the local pulmonary mischief the more hopeful is the climatic treatment, and vice versâ.

3. It is important to inquire whether resort has ever before been had to travel, and with what results. Patients who are braced and stimulated by change of scene, and who possess much mental elasticity, are more likely to gain advantage than those who are depressed and disheartened by absence from home and the association of friends.

Having determined to send our patient abroad, the next question is the choice of a suitable resort; and the selection is becoming increasingly difficult. Our ancestors went to Torquay, Pau, Egypt, or Madeira, according to their inclination and the state of their finances. Now the whole world is laid under contribution. The Riviera, Davos, Algeria, Egypt, Cape Colony, Australia, Tasmania, New Zealand, California, Colorado, Minnesota, Florida, Bogota, Jamaica, Bermuda—all these have their advocates and their statistics of alleged successes.

To keep my paper within reasonable bounds I shall discuss four types only of sanatoria:—

- A. The ocean climate, met with in perfection on shipboard.
- B. The climate of the seashore—e.g., Algiers, Cannes, &c.
- C. The climate of dry inland localities—e.g., Cairo, inland Australia, &c.
- D. The climate of high altitudes—e.g., Colorado and Davos.

A. The ocean climate, such as prevails on the high seas. This climate, of course, presents infinite varieties, according to latitude, but it has some constant features:—

a. It is remarkably equable. Sudden changes of temperature are rare at sea; and ordinary catarrhs and colds (so injurious to the phthical patient) are practically unknown. It is a matter of common observation that on shipboard one can with impunity risk exposure to cold and wet which on land would entail an inevitable penalty.

β. The air possesses a perfect purity and an excess of ozone not to be enjoyed on land.

γ. The barometric pressure is almost invariably high.

It is obvious that we have here a set of conditions eminently favourable for the treatment of phthisis. When we also recollect that on shipboard, in the warm latitudes, patients can spend from 12 to 15 hours daily in the open air, that the stimulating sea air promotes appetite to such an extent that a rapid increase in weight is almost universal, and that there is an almost complete freedom from all kinds of worry and excite-

ment, it is not surprising that long sea voyages should enjoy a high reputation for the cure of pulmonary disease. Theodore Williams states that in his wide experience of phthisis the best results of all have attended the trial of long sea voyages. My own experience—including four long voyages averaging about 12,000 miles each, and the observation of a very large number of phthical patients—is highly favourable to this line of treatment. With few exceptions, the cases which I observed made progress on shipboard, gaining in strength, weight, and comfort, rarely suffering from sea-sickness, and even in the most advanced cases often making a wonderful temporary rally. The disadvantages of a long voyage are the exhausting heat of the Tropics, the monotony of occupation, society, and diet, the absence of privacy, and the scandalously small and uncomfortable sleeping cabins, which are still found even in the best lines.

As regards the particular class of cases most likely to be benefited by a long voyage, I am disposed to think that most patients who retain a fair amount of vigour are likely to gain by this line of treatment, but that it is peculiarly applicable to cases of hæmorrhagic phthisis. An attack of hæmorrhage is an event of extreme rarity on shipboard, whether the equability of the climate, the quiet mode of life, or the high barometric pressure deserves the credit for this exemption. It is a significant fact that, while patients suffering from hæmorrhagic phthisis enjoy an almost complete immunity from hæmorrhage while at sea, they seem peculiarly prone to an attack on landing after a long voyage. This is a sort of axiom among invalids on shipboard, and I have several times seen it exemplified. As regards the best voyage to choose, the only one which can be confidently recommended is that to Australia—all others being either too short or presenting some serious disadvantages. The advantages of the Australian voyage are—1st, length, the average duration being about 80 days by sail and about 45 days by steam; 2nd, a regular gradation of temperature, from the heat of tropical and subtropical latitudes to the bracing and refreshing coolness of the Southern Ocean.

B. The next type of climate favourable for consumptives is the warm marine climate, of which I shall take Algiers as the type, partly because it is a favourable specimen and partly because I have personal acquaintance with it.

The Algerian climate has been described as the best within the Mediterranean basin, and with that opinion my experience, so far as it goes, decidedly agrees. During the winter months the weather resembles that of a genial English summer. Brilliant sunshine without excessive heat, an almost entire absence of frost and cold winds, great equability combined with pleasant variety—all these mark out Algiers as a delightful resort for consumptives. The mean temperature for the winter months averages from 60° to 64°, sudden changes are

rare, and the diurnal range of temperature is so moderate that patients can go out with safety at all hours. The rainfall is considerable, but it comes in occasional deluges of great violence, and long periods of wet are almost unknown.

That the climate of Algiers is infinitely superior to that of the Riviera cannot, I think, be doubted—free as it is from the morning frosts and the blighting Mistral, which occasionally make visitors to Cannes and Mentone wonder why they ever travelled so far from home to be nipped by unexpected frost and mocked by a brilliant sunshine which seems so strangely at variance with the piercing wind. The traveller who halts on the northern shore of the Mediterranean is still among the cold latitudes, still among the regions of winter cold, of snow and frost and rain. But let him cross the great sea—a passage of about 30 hours—and he feels at once that he has reached the region of eternal summer, where fruits and flowers flourish in subtropical luxuriance, and where the swarthy faces around him serve as a reminder that he has touched the verge of the Dark Continent.

The climate of Algiers is drier than that of most maritime localities—a circumstance which is, no doubt, due to the proximity of the great desert. It is almost quite free from cold winds, and the sirocco (which is such a scourge in summer) is almost unknown in the winter months. While in Algiers I had the novel and not unpleasant experience of being rocked by an earthquake, but this also is an event of great rarity. As illustrating the mildness of the winter climate of Algiers, I may mention that on Christmas Day I enjoyed a swim in the Bay of Algiers, and found the water pleasantly warm.

Apart from considerations of climate, Algiers presents many attractions. The situation of the town is remarkably picturesque, and the invalid need never tire of gazing from the elevation of one of the villas of Mustapha or the village d'Isly over the beautiful bay, studded with the sails of feluccas and backed by the imposing ramparts of the Djur-djura mountains.

Flowers and fruits grow in great luxuriance, and the variety and excellent quality of fresh vegetables (which can be obtained all through the winter months) is a point of real importance to the invalid. One of the recollections which is likely to remain for ever impressed on the mind of the visitor to Algiers is the fact that he was there able to enjoy fresh green peas on Christmas Day.

If the tourist goes into one of the bazaars of Algiers and makes a small purchase he often receives as change an extraordinary medley of coins of different countries. This variety is typical of the remarkable mixture of races which one encounters in Algiers—Arabs, Kabyles, Moors, Negroes, Maltese, Frenchmen, Spaniards, Italians, Turks, Englishmen. I hardly know if even this enumeration exhausts the list. Thus, if the invalid has

any taste for studies of race he has an unrivalled field open to him.

Then again, if antiquarian studies interest him, Algeria has rare attractions. The country has had a stirring history, from the days of Carthage down through the times of the Vandals and Arabian Caliphs to the modern days of French dominion, and the antiquarian remains are numerous and extensive. Only those who have never wintered abroad will think that I am attaching undue importance to these points. Often the greatest trouble of the invalid is the lack of congenial occupation and the consequent ennui, and no wise adviser will send a patient to a health-resort which has only climate to commend it, and which is entirely destitute of objects of interest and attraction.

As regards the particular class of cases benefited by the Algerian climate I regret that I cannot lay down any fixed rules. A large proportion of cases certainly do well, but I am not aware that any marked preponderance of advantage can be claimed for any special type or stage of phthisis.

Australia has long had a great repute as a locality for consumptives, and many remarkable cures have attended the resort thither of patients from these islands. Nevertheless some authorities denounce Australia, and regard it as hurtful to the phthisical patient. The error lies in talking of Australia as a whole. One might as well talk of the climate of Europe as of the climate of Australia. In so vast a country the gradations and variations of climate are necessarily endless; and while some regions, such as the sea-coast especially near Melbourne and Sydney, are decidedly noxious to the consumptive, other regions, such as the Darling Downs of New South Wales and the vast plains in the interior of Queensland, possess an intensely dry, equable, inland climate, like that of Upper Egypt, presenting an assemblage of conditions highly favourable for the successful treatment of phthisis.

The climate of Melbourne and Sydney, especially the former, is decidedly injurious, as the summer heat is there excessive, and sudden changes of temperature—I have myself seen the thermometer fall 40° in thirty minutes—are frequent. Dust-storms are common in the summer season, and are peculiarly distressing to all sufferers from respiratory disease. The consumptive who tries Australia should be recommended to spend as little time as possible in the cities on the coast, but at once to push on to the inland regions, or else to cross Bass' Straits to Tasmania, where he will enjoy one of the mildest, most equable and altogether most charming climates in the world.

D. I have lastly to speak of the effect of residence at high altitudes in the treatment of phthisis, and I shall restrict myself to Davos, in Switzerland. Here I cannot speak from personal experience; but I have had the advantage of frequent intercourse with those who know Davos well, and my information is as good as any sec-

Ulster Medical Society
Session 1883–1884
President Robert Foster Dill

ond-hand information can be. Davos, as most people are aware, is an elevated valley in the Canton of the Grisons, in the east of Switzerland, and is at an elevation of 5,200 feet above the sea level. A local authority thus describes the chief characteristics of the climate:—"The lightness of the air (one-fifth less than at sea level), its extreme purity and dryness, the remarkable absence of clouds (pleasantly illustrated by long periods of brilliant sunny days), the great amount and comparative uniformity of solar radiation, enabling invalids to spend most of their time out of doors, and even in the depth of winter to sit in the open air for many hours daily, and the bracing, tranquil atmosphere, undisturbed by cold winds—all combine to constitute a sanatorium as nearly perfect as can be found."

The following statistics about the climate of Davos cannot fail to be interesting and instructive. The figures are based upon the average of three years:—

1. Average number of cloudless and sunny days:—October, 11; November, 15; December, 16; January, 19; February, 16; March, 17.

2. Average number of days of alternate cloud and sunshine:—October, 12; November, 7; December, 8; January, 9; February, 8; March, 8.

3. Average number of windless days:—October, 14; November, 22; December, 25; January, 25; February, 17; March, 12.

4. Average number of cloudy days:—October, less than 1; November, 2; December, less than 1; January, less than 1; February, none; March 1.

5. Average number of wet and snowy days:—October, 2; November, 3; December, 1; January, 2; February, 2; March, 2.

6. Average number of days on which some rain or snow fell:—October, 5; November, 4; December, 5; January, 1; February, 2; March, 4.

The average height of the barometer is from 24 to 25 inches.

As the best commentary on the above statistics I shall quote some portions of a letter which I have lately received from Davos, bearing date December 7th, 1883. My correspondent is a medical gentleman who has made a marvellous rally after the disease had rapidly progressed to the third stage, and his information is based not only on personal observation, but on the best medical opinion to be obtained in Davos:—

"As regards the cases which do best here, one cannot honestly draw the line; the reason being, that where there is sufficient vigour in the system to resist the cold, almost all classes of cases do equally well. Where the disease has reduced the vital powers very low the circulation cannot be carried on sufficiently in this climate, and such cases do badly; but I fear for them no suitable climate exists. Hæmorrhage cases in the early stage certainly do well. There are people living here who cannot live in the valleys, or anywhere at the sea level, without rapidly developing hæmorrhage. Chronic

pleurisy and pneumonia cases get on well—in fact, perhaps best of all. The air seems to be almost a specific for causing the absorption of the fibroid material formed in a case of chronic pleurisy. Very many of the cases here are patients with catarrhal pneumonia of both apices, and they usually progress favourably. Cavity cases are perhaps the most interesting, as they form elsewhere the least successful class of all. Here, when the cavity is not very large or the patient hopelessly weak, cicatrization is the rule. In ordinary consolidation the exudatory products are some times absorbed with wonderful rapidity. The great advantage of this climate is its dryness. It is perfectly wonderful how tolerable extreme cold is when the air is dry. Were Davos as damp as London we should all be corpses in a week; but one shivers more in England in the summer than here during the entire winter. It is certain that the cold is invigorating, and that digestion is thereby improved, assimilation increased, and fat accumulated, and, further, that the snow prevents exhalations of decaying substances from the earth. The absence of dust and the bright sunshine are useful adjuncts, but I think the dryness of the air is the chief point. The cold has been alleged to act as a vermicide to the bacilli."

Evidence such as this cannot be gainsaid, and I shall not weaken it by comment. While the exposure to cold of patients suffering from a disease for the cure of which warmth has usually been regarded as an indispensable condition, is a novelty, and as such is sure to excite opposition more or less reasonable, the proofs of the efficacy of the climate of Davos are yearly accumulating, and can no longer be disregarded by the most prejudiced persons. I have not left myself time to sum up my results, but it is hardly necessary to do so. I have already indicated my views with sufficient exactness.

I have no high opinion of the south of France, and am disposed to question if it is much superior to the health-resorts of the south of England. Cannes and Mentone are probably the best of the French stations; and I may here remark that Pau and Montpellier are rightly losing whatever repute they ever possessed. The Italian resorts are not much better, and of these Sorrento is perhaps the favourite. Of Egypt and Madeira I cannot speak, and I think where practicable our choice should lie between the long sea voyage, Algiers, Australia, or Davos. I have already endeavoured to indicate the main indications which must guide our choice in this most vital matter, involving, as it does, both the life of our patient and our own professional reputation.

Since last meeting a most successful dinner was held on 4th inst (Tuesday evening) 7 o'clock at "The Castle Restaurant". 31 members and guests sat down to dinner—10/- and 15/-.

R. F. Dill, President
8th January 1884

1884 Third Meeting was held upon January 8th

(Tuesday).

Professor Dill (President in the chair), present Drs. Wheeler, McFarland, T. Kennedy Wheeler, Dwyer, Dempsey, St. George, Fagan, McConnell, Whitla, Esler, O'Neill, J. W. Browne, McHarry, Lindsay, and Mackenzie, Secretary.

Dr. Kennedy Wheeler exhibited a patient the subject of chronic inflammation of knee joint treated by "Sager's splint".

He also showed patient whose leg was flexed at a right-angle for years. The patient had now a comparatively useful limb.

An interesting discussion followed in which Drs. McFarland, J. W. Browne, Fagan, Esler and the President took part.

Dr. Whitla showed liver with malignant disease and abscess. He gave a clear and detailed account of the symptoms, duration of illness etc. of the patient from whom the liver was taken.

Dr. Dempsey thought it possible that the disease was tubercular.

J. W. Browne showed drawing of large arterial nevus extending over almost the right side of head and face of a child. He described his mode of treatment by the thermal cautery needle.

Dr. Browne also showed an external abdominal ring which he had sutured for radical cure of hernia some years ago.

Dr. St. George read a paper on "Some remarks on bronchitis".

Paper:¹ Bronchitis is a very prevalent complaint, and not only is it of frequent occurrence in different persons, but one of its chief characteristics—and perhaps its most formidable one—is its great tendency to recur again and again in the same person, and often at the same periods of time, the attacks increasing in severity and duration from year to year, until at length the sufferer is scarcely ever entirely free from their effects, and becomes gradually disabled from all active employments.

Moreover, in estimating the importance of a thorough study of this disease, we must not overlook the fact of its peculiarly wide and intimate relations with other diseases both of the lungs and of other organs, and with several of the commonest forms of dyscrasia to which the human frame is liable.

Bronchitis, as we are all well aware, is essentially an inflammatory affection of the bronchial mucous membrane, attended with more or less of flux from the inflamed surfaces. As regards its usual symptoms and physical signs, I shall not now enter into any separate detailed exposition: we are all familiar with them; and it will be more convenient to incorporate any explanations which I may deem it desirable to make on these points with other practical comments on the cases

which I shall quote in illustration of my subject. But though bronchitis is always manifested by somewhat similar symptoms, and is therefore pathologically known by one name, it is by no means of uniform character in different persons, but varies much in extent, intensity, and duration. Thus it may be limited to the larger bronchial tree, or it may extend to the capillary tubes.

It may be a more or less severe, acute attack, running a comparatively rapid course, and ending in perfect recovery; or it may assume a sub-acute or a chronic form, and its duration be indefinitely protracted. In its severer forms it is a very fatal disease, especially to the young, the delicate, and the aged. In its milder forms it is attended by no immediate danger to life; but as a bronchial membrane which has once been inflamed is very prone to a recurrence of inflammation from comparatively slight causes, even a mild attack of bronchitis may, especially in persons whose health is otherwise not perfect, become the starting-point of a chronic bronchial affection, and thus lay the foundation for a life-long delicacy, or for various secondary ailments.

In the next place, although the general symptoms of bronchitis are always very similar, inasmuch as it is always the same structure which is the seat of irritation, this irritation may be produced by various causes—some proceeding from without, and others from within the organism—some accidental, and others constitutional. One cause, above all others, produces, especially in this locality, an immense amount of bronchial disease—I refer to the fine dust and fluff inhaled by the operatives in the large flax spinning mills of this and neighbouring towns. Vicissitudes of weather and exposure to cold or damp are, however, generally regarded as the only exciting causes of bronchitis. Sometimes such exposure is, in fact, the only cause, as when an attack of bronchitis results from remaining for some time wet-shod, getting chilled, or wet through on a journey, or else from passing, without proper precautions, from the hot, dry air of a house to the cold or damp atmosphere out of doors. And again, it is notorious that vicissitudes of weather, such as the setting in of a cold, biting east wind after great heat, often serve as an exciting cause of bronchitis. Nevertheless there can be no doubt that in the majority of cases such causes only excite the disease when a strong predisposition to it already exists, either from some constitutional derangement of health, or else from delicacy of the bronchial membrane consequent on previous attacks of bronchitis or on long-standing local irritation arising from the inhalation of dust, &c. I am, besides, well assured from careful observation that bronchitis is sometimes the direct consequence of some constitutional vice apart from exposure to any external exciting cause. In confirmation of this opinion I may remind you that bronchitis, although certainly far more

¹ [Dublin Journal of Medical Science, 1884, v77, p410.]

prevalent in the colder season of the year, is by no means peculiar to it, and in some cases even has a definite tendency to recur periodically in summer instead of winter, and usually on such periodical recurrence to be associated with some well-marked constitutional disorder. I have already alluded to the intimate relations between bronchitis and various other ailments, local and constitutional. These relations may be either of cause or consequence, as when, on the one hand, bronchitis produces some secondary lesion either of the lungs or heart, or some more remote sequence, such as disease of the liver or kidneys; or when, on the other hand, bronchitis is itself the secondary result of some constitutional vice, such as gouty syphilis, or some local affection, such as cardiac or renal disease. Bronchitis may thus be either a primary or a secondary affection—primary, as when it is the result of exposure, or when the irritation, excited by the inhalation of dust, &c., develops the disease; secondary, as when the bronchial affection arises out of some previously existing ailment, such as any of those I have just mentioned. Again, bronchitis may be associated as a complication with other diseases, as measles or whooping-cough, or with other pulmonary affections, such as pneumonia or phthisis.

The subject indeed is such a wide one that I do not purpose, neither would it be possible for me, to enter into its consideration exhaustively in the compass of a paper like this; but I make these few observations with the hope of drawing attention to the great practical importance of studying a disease, the variety of causes, complications, and consequences of which must obviously render the diagnosis, prognosis, and treatment equally various in different cases.

In order to bring the several relations of bronchitis to which I have alluded more plainly before you, I will, with your permission, read notes of a few cases illustrative of them, which have come under my notice in the County Antrim Infirmary, and in my private practice:—

Case I.—D. L., aged thirty-six, mechanic, was admitted under my care into the Co. Antrim Infirmary, on June 16th, 1880. About six 4 years previously, after a very warm day's work, and while still perspiring freely, he bathed in the River Lagan. He was attacked at that time with a severe cold, and since then has been subject to a cough, from which indeed he is now seldom free. This chronic cough is at any time easily aggravated by exposure; and he has been laid up more or less with it every winter. There is no family history of phthisis, and he has never suffered from gout or rheumatism, nor indeed from any other ailment, except bronchitis. On admission he complained of dyspnoea, and had a frequent hard cough, attended by the expectoration of a thin, transparent, frothy mucus, mixed with opaque yellow masses; skin cool; pulse 72. The chest was well formed, and rose equally and evenly on both sides dur-

ing inspiration, but the breathing was laborious, the sterno-mastoid and scalmi muscles acting powerfully as elevators during inspiration, and the supra-clavicular regions being depressed at the same time. But although the breathing was thus difficult, it was not accelerated in proportion, there being only twenty-four respirations per minute. These symptoms are all characteristic of bronchitis. Both in pneumonia and progressive phthisis the skin is usually pungently hot; whereas, even in the febrile stage of acute bronchitis, when uncomplicated with either pneumonia or tubercle, although the temperature may be raised, the skin seldom conveys to the hand any remarkable sensation of heat; and in cases such as this one, frequently does not exceed the normal warmth. The pulse also in bronchitis never rises as high as in phthisis or pneumonia; and very often, in cases of a chronic character, does not exceed the normal frequency.

Again, though the respiration is generally much quicker in the other pulmonary diseases than it is in bronchitis, yet it is never so laborious. Even, with greatly accelerated respiration, patients suffering from pneumonia are often not conscious of dyspnoea; whereas, in severe bronchitis, laborious breathing is the rule. With respect to the nature of the expectoration, the thin, transparent, frothy expectoration is indicative of recent bronchitis, or rather of a recent attack engrafted on an old chronic affection, as is shown by the frothy expectoration being mixed with the opaque yellow mucus characteristic of chronic bronchitis. In order to complete the history of this case there are two other points to which I must allude. The front of the chest was resonant on percussion from apex to base on both sides; distinct pulmonary resonance being elicited by percussion, even over the cardiac region. The percussion note was also clear posteriorly. The respiration was feebly heard over the left mammary region; in other places it was sometimes harsh, and it was everywhere more or less sibilant. The heart was seen beating immediately below the xiphoid cartilage. The heart sounds were feeble, but free from murmurs. This displacement of the heart was evidently due to emphysema, the presence of which was indicated by the abnormal clearness over the whole front of the chest, with slight enlargement of the right side of the heart. As regards the treatment and progress of this patient, I may say that he improved under a mild antiphlogistic and tonic treatment, consisting of at first the following mixture three times a day:—

R. Tr. scillæ, ℥. xv.
Sp. æther. nitr., ʒj.
Liq. amm. acet., ʒij.
Tr. hyoscyam., ʒss.
Aq. camph., ad ʒj. M.

As soon as the urgent symptoms had subsided, I substituted the following:—

R. Acid. nitro-hydrochl. dil., ℥. x.

Tr. hyoscyam.

Tr. laticis, āā. ʒss.

Inf. gent. c., ad ʒj. M.

To be taken three times a day.

Under this treatment he improved, and was discharged, relieved, in about six weeks.

This case belongs to a class in which great benefit may be derived from medical treatment during exacerbations of the bronchial affection, and in which much may be done by care and proper management to retard the progress of the disease; but in which the disease itself has too firm a hold to give us much hope of being able to effect a permanent cure, especially in persons liable to exposure. I have little doubt that on the first such occasion my patient will suffer a fresh return of his malady, and find his way for relief to me, or some other medical man. I will now draw your attention to a case drawn from a class very common in this part of Ireland; I allude to bronchitis caused by the inhalation of dust mixed with fine particles of flax.

Case II.—R. M., aged forty, hackler, was admitted under my care into the Co. Antrim Infirmary on April 20th, 1883. His work consists in drawing the flax after it has been scutched through a series of iron pins, so as to remove the rougher parts. As the workman stands before these pins, and swings the flax up and down in front of his face, it is evident that a large quantity of the fine particles must be constantly inhaled. Attempts have been made to induce the flax-dressers to wear respirators whilst at their work, but to no purpose.

He had long suffered from cough and tightness of breathing, and latterly also from difficulty of breathing.

At the time of his admission his skin was cool, and pulse quiet, the expectoration scanty, opaque, and of a yellow colour. The chest was resonant on percussion, both in the anterior and scapular regions; but there was a slight degree of dulness over the bases of both lungs posteriorly. The respiration was feeble in the apex of the right lung, and harsh in the apex of the left. The respiration was tubular near the right nipple, and coarse crepitation was heard over a limited space near the left. There was fine crepitation in the base of the right lung, and a large mucous rāle in the corresponding part of the left; urine normal. He was ordered a mixture, containing in each dose, three times a day—

R. Ammon. carb., gr. 5.

Tr. scillæ.

Tr. camph. c. āā, ℥. xv.

Inf. senegæ, ad ʒj. M.

In about a fortnight, as he had improved, I gave him two drachms of cod-liver oil after each meal, and as a tonic before food a mixture containing—

R. Acid. nitro-hydrochl. dil.

Tr. camph. c. āā, ℥. x.

Vin. ipecac., ℥. vi.

Inf. gent. co., ad ʒj. M.

I carefully examined him on the 22nd May, when I

found the cough and dyspnœa greatly decreased. The moist sounds in the base of the left lung had given place to harsh dry respiration. The crepitation near the left nipple had disappeared, and the fine crepitation in the base of the right lung had become coarser, and less extensive. He continued to improve until the end of June, when he considered himself convalescent, and resumed his work.

I had under my care about two years before this a patient who remained longer under my care, and the history of whose case is more conclusive as to the cause of his complaint and the remedy for it

Case III.—J. W., aged twenty-two, a flax-dresser in a mill in Lisburn, consulted me on the 12th June, 1879. His work was much the same as that of the preceding case. He had only followed this employment for eighteen months, and had previously been quite healthy, but had frequently during the year previous suffered from bronchial irritation. For several months before he had consulted me he had been troubled with much difficulty of breathing, and dry cough, attended by an opaque muco-purulent expectoration, which of late had been frequently streaked with blood.

On examination, he had a follicular sore throat, and a husky voice. His chest was well formed and normally resonant on percussion over its whole anterior aspect; posteriorly the resonance was also normal. The respiration was dry and sibilant in front; sonorous rhonchus was audible behind. Over the lower lobes of both lungs, and on the left side as high as the scapula, no moist sounds were anywhere heard. He was put on nearly the same medical treatment as the last patient, and was advised to change his occupation, which, in the meantime, he promised to discontinue. On June 26th the cough and expectoration had decreased. Rhonchus was still audible between the scapulæ, and in the lower lobes of both lungs. The respiration over the front of the chest was still dry and sibilant; expiration prolonged. By July 9th the rhonchus in the back had much diminished; he then went to Newcastle for change of air, and, on his return, reported himself quite well, and resumed his work, which he persevered in for several weeks. On Sept. 11th he returned with much cough, shortness of breath, and wheezing, especially at night.

The expectoration was more copious than before, thin, and frothy. He said his present attack had come on gradually, the first symptoms having been pain, and oppression over the sternum, which had appeared almost as soon he recommenced work. There was no hæmoptysis. His chest was still normally resonant on percussion; but the respiration was harsh and sibilant as before. I warned him again, that if he wished to enjoy good health, he must give up his present employment. On Sept. 25th he reported to me that he was greatly relieved, and on October 16th he informed me that he had obtained work in another part of the factory, where he was free from dust, and there was

already a manifest improvement in his symptoms—the cough and expectoration having much abated. I have had many opportunities of seeing him since, and he has continued in fair health.

We cannot fail to remark the very different degrees of rapidity with which this disease advances, and we perceive that this difference is due in part to more or less frequent occurrence of catarrhal accidents. Other circumstances peculiar to the patient—such as age, habits of life, and constitutional tendencies—are not without great effect on the progress and course of the disease, and of these the last-named especially exercise a most important influence in promoting and modifying its development. We can easily understand that the existence of any constitutional conditions must lessen the power of resistance, in the bronchial membrane, to the mechanical irritation exerted upon it, and thereby not only hasten the development of the disease, but add to its severity.

On the other hand, if there be any tendency to tubercular disease, I can conceive nothing more likely to light it up in the lungs than such bronchitic irritation; and I have, in fact, in a few instances, seen the constitutional tendency and the mechanical existing cause in operation together, and have only been enabled by the history of the case to determine the coexistence of the two factors. The cases I have referred to are drawn from the poorer classes, but I am persuaded that the causes of the bronchial affection in all these patients are, within certain limits, in much commoner operation than might at first sight be supposed. Few private patients are exposed to these noxious influences in sufficient intensity to excite bronchitis directly, but very many unsuspectingly inhale dust or impure air to a degree which gradually produces slight bronchitic irritation, and renders them exceedingly liable to contract bronchitis on being exposed to any exciting cause.

Even the habitual travelling along a dusty road is apt to have this effect, and the constant breathing of hot and dry air in dwelling-rooms, especially if combined, as is too common, with imperfect ventilation, is a fruitful source of the same tendency. The employment of gas in apartments, unless proper appliances be in use for carrying off the products of combustion and for admitting fresh supplies of pure air, produce a dangerous state of the atmosphere. These are things of no small consequence to be borne in mind in private practice.

It is still common for bronchitic patients to shut themselves up in close, hot rooms, and breathe impure air, with the idea that by so doing they are thereby avoiding draughts, although, in fact, they are aggravating their ailments by so doing, and retarding their cure.

No doubt there are cases in which we find it necessary to keep our patients for a time in an artificial temperature, but we should take care that while the air of

the apartment is warm it should never be allowed to become dry. Even the simple device of keeping a kettle of boiling water on the fire, with a tube long enough to throw a constant jet of steam into the room, will suffice to moisten the air, and with proper contrivances ventilation may be always obtained without danger to the most susceptible patient.

By far the greater number of bronchitic patients, however, actually do better when not kept in rooms at too high a temperature, inasmuch as they sustain less injury to their general health, and are able to go about earlier, and with less risk of taking cold from any slight exposure, than those who have been so confined.

It is not so much a warm as a moist atmosphere that is needed by bronchitic patients, with ample protection from chilling of the surface, and this may be secured by suitable clothing. In fact, as a rule, I have found that, all things being equal, bronchitis is slower in its progress, and less speedily affects the general health, in persons whose duties take them much out of doors, than in those who, from their in-door employments, would generally be presumed to be less exposed to causes of taking cold, and less liable to attacks of their complaint.

I will now make a few remarks on the treatment of the class of patients I have brought under notice. When patients come under my care with an acute attack of bronchitis, I find it best to act on the skin, to promote expectoration, and relieve the inflamed mucous membrane. For this purpose, if the pulse be of good volume, and the patient's strength not impaired, I give a mild diaphoretic mixture of Mindererus' spirit, antimonial wine, and tincture of henbane, and occasionally a little ipecacuanha wine.

If, however, the patient be depressed, I give the *vinum ipecacuanhæ* without the antimony. Later on, or in less acute cases, I find the more stimulating expectorants, as squill, the most effectual; but in almost all cases, especially in chronic bronchitis, a time arrives when expectorants cease to be useful. The expectoration indeed continues, but it rather is of the nature of a habitual flux than the result of active irritation.

The treatment now requires to be of a tonic character, and though zinc, iron, or quinine, are all useful, I have found the mineral acids, especially the dilute nitro-hydrochloric acid, in combination with a vegetable bitter, as quassia or gentian, the most advantageous. In chronic cases attended by very copious expectoration, balsamic remedies, as gum ammoniacum, &c., are often of service, but I have found them, as a rule, apt to disagree with the stomach, and as the digestive powers are in such cases often feeble, I have been accustomed to give tincture of larch in mixture, or tar in two-grain pills, which never disagrees, and is equally, if not more serviceable to the bronchial affection.

Its effect is not only to lessen the expectoration, but also

apparently to restore the debilitated membrane to a more healthy tone, and to render patients less liable to attacks of catarrh.

Useful as medicines undoubtedly are in allaying or curing attacks of bronchitis, I need hardly tell you that whenever the bronchial affection is even partially referable to an existing external cause, no permanent good can be effected without the removal of that cause.

Amongst the working classes it is often impossible to accomplish a change of employment, though I have seen cases, such as the one I have related, in which a change of occupation has been effected, and the patients have recovered; but amongst the higher classes much may be accomplished—I say whenever the bronchial affection is even partially referable to an external cause, because, as I have said before, cases of primary bronchitis are comparatively rare. Even amongst hospital patients external causes in a large majority of cases only develop or aggravate constitutional or hereditary tendencies to bronchial disease, and this naturally obtains more among the upper classes, who are exposed to such causes only in slighter degrees.

Time will not permit me to do more than refer to a few cases of gouty bronchitis. I have mentioned before that in a large number of cases bronchitis is a secondary, and not a primary disease—that is to say, a disease arising out of some other previously existing ailment or constitutional dyscrasia.

As in the beginning of this paper I have touched upon examples of primary bronchitis arising solely from exposure to external exciting causes, I now therefore purpose to consider gouty bronchitis. All these cases which I will now refer to have suffered either from gout or chronic rheumatic gout. I am indeed aware that some of our highest authorities consider regular gout and rheumatic gout as entirely different complaints, and no doubt there is a pathological distinction between them, but clinically regarded they are allied ailments affecting the same tissues, and often seeming to occur in members of the same family as manifestations of a common hereditary diathesis.

Case IV.—E. M'K., a carpenter, aged fifty, became a patient in the County Antrim Infirmary, on Dec. 1st, 1882. His father had been a butler, and suffered from gout, and died from asthma, aged sixty-six. One of his brothers suffers from rheumatism, and another from chronic bronchitis.

The patient himself had had several attacks of rheumatism and sciatica. He had also for years been subject to a severe cough in winter, which usually began in October, and lasted till March. The cough was attended with much dyspnoea, and by frequent paroxysms of the same at night.

These generally came on at one or two o'clock in the morning, after he had been asleep, compelling him to sit up in bed for a longer or shorter time. The parox-

ysms of dyspnoea are not, as a rule, common in bronchitis.

Dr. Graves, in his "Clinical Lectures," says that he scarcely ever met with a patient who had been subject to chronic bronchitis who did not also labour under more or less asthmatic dyspnoea, but it is more than probable that Dr. Graves used the term for the dyspnoea, which is commonly attendant on chronic bronchitis, especially when complicated either with pulmonary emphysema or with cardiac disease, and which is only paroxysmal, inasmuch as it is aggravated by every physical exertion, and by every accession of catarrh.

So far as I could learn, it was in this latter sense that my patient applied the term asthmatic to both his parents. At the same time, asthma, like bronchitis, is often connected with a gouty diathesis, and I have no doubt that in this patient this diathesis was the cause of both complaints. At the time of his admission the patient's skin was cool. Pulse, 85; respiration, 86. His cough was troublesome, and his expectoration thin, white, and frothy, but, he said, more generally thick, and of a yellow colour, and had sometimes been streaked with blood.

On examination his chest was found to be broad and deep. The veins of his thorax were turgid, and most markedly on the left side, and respiration was laboured.

He said he was never free from dyspnoea, even in summer, especially in hot weather. The percussion note was clear over the whole front of the chest, especially in the mammary regions, and the clear sound encroached somewhat on the normal cardiac dulness. Posteriorly there was resonance on percussion, excepting over the base of the left lung, where it was slightly deficient. The respiration was harsh, expiration prolonged. Rhonchus was more or less audible over both lungs, and moist sounds were heard with inspiration in the base of the left lung.

The heart's apex was somewhat depressed. His urine was not albuminous. The patient continued under treatment until February, when he was discharged almost well as regards the bronchitis, and without having any return of the symptoms of rheumatism or sciatica.

It is indeed true that the gouty form of dyscrasia is exceedingly common not only amongst private patients, but also the working classes. But, common as it is, gout is found in a very much smaller proportion of the total number of our hospital patients than of the bronchitic class of patients taken by themselves; hence I think I am justified in the conclusion that there is really an intimate relation between a gouty constitution and chronic bronchitis, and that in many cases in which a hereditary tendency to gout has not been developed into the characteristic form of that disease it manifests itself in the form of chronic bronchitis. In further support of these views I may mention that I have fre-

quently known bronchitis and gout or rheumatism habitually to alternate, an obstinate attack of bronchitis sometimes subsiding on the occurrence of a fit of gout, and again at other times a smart fit of gout being relieved by the development of bronchitis.

There was an elderly man for a long time under my care. His ailments were rheumatic gout, eczema, and bronchitis, and he was rarely, if ever, free from some one of them. No two of the three were ever present together; but just as he was congratulating himself on having got rid of the rheumatism, his legs would be attacked with eczema, and this would disappear in a few weeks, to be succeeded by an attack of bronchitis.

I will now mention one or two cases à propos of this form of bronchitis:—

Case V.—H. M'C., a wheelwright, came under my care in 1876. He had then been ailing a year and a half, during which time he had suffered alternately from cough and what he called rheumatic pains in his knees and elbows. At the time of his consulting me he had slight cough and dyspnoea, but he principally complained of gastralgia of some weeks' standing.

The pain came on soon after eating, and was excessively severe. This gastralgia, I may observe, was doubtless but a different manifestation of the same disorder of health which induced the bronchitis and the so-called rheumatic pains. This form of dyspepsia is very common in persons of gouty diathesis, who have never had paroxysms of acute gout, and, like other forms of the disease, may either give place to some new train of gouty symptoms, or be relieved by a fit of gout itself. On this occasion the patient was soon relieved from his ailments by the use of bismuth, &c., in combination with a bitter infusion, and of small doses of blue pill and rhubarb, but he returned to me on May 27th of the same year, with pain and tenderness in the soles of his feet, and with lepra on the arms and knees. He said he had of late suffered but rarely from gastralgia, and only then in very slight degree; neither had he any cough, but he was not free from dyspnoea. I gave him 10 grains of iodide of potassium, with 5 minims of colchicum wine three times a day, to which, as the pains abated, I added small doses of arsenic. On July 22nd the pains had for some time entirely left him, and the eruption was gradually disappearing, but he had again begun to cough and expectorate, and he complained of increased shortness of breath. The chest was normally resonant, but harsh rhonchus was audible throughout both lungs. He was ordered small doses of liq. arsenici hydrochlorici and acid, hydrochlorici dil. with cod-liver oil, and some extract of hemlock at night to allay the cough.

He was soon relieved, and ceased to visit me. Late in October he again consulted me for lumbago and pains in the knees and elbows, having then no cough, but the lepra, which had never altogether left him, was much increased.

As these ailments yielded (after about five weeks' treat-

ment), he once more began to cough, and suffered from bronchitis throughout the winter. On the 20th April, 1877, he was quite free from pain and the lepra, and had only a little cough and expectoration on first rising in the morning. I now put him on a course of dilute nitro-hydrochloric acid and tincture of larch, and he was quite well in June.

I have already said that when bronchitis occurs in persons of gouty diathesis, it frequently happens, on the one hand, that bronchitis makes its appearance on the subsidence of the gouty symptoms; and again, on the other hand, that a fit of gout relieves the bronchitis. The following case illustrates the latter mode of alternation:—

Case VI.—W. J. B., aged sixty, brewer, was admitted into the County Antrim Infirmary, October 22nd, 1880. He stated that he had for many years been subject to cough and expectoration, with great dyspnoea, in summer as well as in winter, as much in hot as in cold weather. A medium temperature suited him best, extremes always increasing his distress. He had had regular gout for the first time twenty years previously, and said he was in the habit of suffering from gouty pains in the hands and feet, but he was free from them when admitted. He was also subject to occasional psoriasis.

On inquiry he admitted that he drank a great deal of beer and porter, as he was brought in contact with it in his business. The patient himself referred his complaint to exposure to cold during his work, but the sudden appearance of the gout having preceded that of the bronchitis, and it having been accompanied or followed by gout in three attacks out of four, we may reasonably assume that these exposures were, at most, only the immediate exciting causes of irritation in a bronchial membrane already predisposed to disease by existing constitutional derangement. When admitted, he was suffering from a pretty severe attack of bronchitis, attended by much dyspnoea and by a copious frothy expectoration; but he said that though he was never altogether free from expectoration any more than free from cough, it consisted, during the intervals between the more acute attacks, of only a small quantity of thick, transparent, bluish mucus. Now, this is the exact counterpart of what we meet with every day in bronchitis, more particularly in those who have also a gouty constitution.

They habitually cough up in the morning, and, it may be, at rare intervals through the day, little pellets of tenacious, bluish, starch-like mucus, sometimes studded with darker specks. This ailment, which may be perhaps almost too slight to attract the patient's notice, is quite compatible with good health in all other respects, but it is nevertheless the proof of an abnormal condition of the bronchial membrane. In the healthy state only just as much fluid is secreted as is necessary to keep the bronchial membrane moist enough for the

due performance of respiration. We may therefore safely assume, as a rule, that wherever there is expectoration, however small in quantity, the membrane is not in a state of perfect health, and therefore is far more liable than a membrane in the normal condition to suffer from any intermediate exciting causes of bronchitis of whatever kind. But to return to my patient. I treated him successively with carbonate and infusion of senega, then with dilute nitro-hydrochloric acid, tincture of gentian, ipecacuanha wine, and tincture of henbane.

On December 11th he was in all respects greatly improved, and passed from under my care on January 16th of the next year.

He came to me again on May 6th of the same year, suffering from gout of the fingers of his left hand, and also from cough, attended by the white, frothy, and mucous expectoration characteristic of recent bronchitis. There was also slight œdema of the ankles, but the urine was free from albumen.

The chest was found on examination to be normally resonant on percussion. Sibilus and rhonchus were more or less audible throughout both lungs. The expiration sound was prolonged, especially in the upper lobes, and mucous crepitation was heard in the base of the right lung. Taking into consideration the mixed character of the illness, showing the actual coexistence of gout and bronchitis, I prescribed a combination of medicines calculated to meet both aspects of the case—that is to say, I gave 4 grains each of potassium iodide and carbonate of ammonia, 10 minims of colchicum wine, and 20 minima each of tinctures of squill and henbane in an ounce of camphor water, three times a day, and 2½ grains each of extract of hemlock and pill of ipecacuanha and squill every night. This is a plan of treatment which, modified according to circumstances, I have found often very serviceable in similar cases, and under it the patient gradually improved; but at the end of a fortnight, his appearance being anæmic, a grain of sulphate of iron was substituted for the ammonia in each dose of his mixture. The gout soon disappeared, but the mucous crepitation in the base of the lung still continuing without change, I ordered him a mixture containing 20 minims each of liquor ferri perchloridi and tincture of henbane, and 10 minims each of vinum ipecacuanha and acidum hydrochloricum dilutum in an ounce of infusion of quassia. He now rapidly recovered, and continued well, and was discharged in August.

He next returned on 5th May following, when he was admitted in an almost similar condition. The finger joints were swollen and painful, and he was suffering from cough and dyspnœa. The bronchitis was, however, in a more advanced state, the expectoration being now thick, opaque, and muco-purulent, instead of glairy and frothy, as on his previous admissions. He was treated in a similar manner, but improved more

slowly than the year before. The cough varied from time to time; but though better on the whole, was by no means gone when, towards the end of June, he was attacked by gout in a more pronounced and regular form, affecting successively the balls of both great toes, the ankles, and fingers. On the appearance of gout in this acute form the cough and expectoration at once abated, and I ordered him as a mixture, three times a day, the following

R. Ferri sulph., granum.

Potass. iodid., gr. 5.

Vin. colchic., ℥. xv.

Glycerin., zj.

Aq. menth. pip., ad ʒj. M.

and a pill at bed-time, consisting of two grains of acetous extract of colchicum and three grains of Dover's powder. This treatment he continued, with some modifications, for a month, when he was discharged cured. But his relief was only temporary, as he returned on December 5th. His cough had returned, with much wheezing and dyspnœa, and with the frothy transparent expectoration I have described as characteristic of bronchitis.

His skin was cool; pulse 90, but quite regular. The sides of his chest rose evenly in respiration, and were equally and normally resonant on percussion. The heart sounds were normal; rhonchus and sibilus were audible over the lower lobes of both lungs posteriorly, intermixed with faint mucous crepitation in the base of the left lung; urine was normal. At this time he was quite free from gouty pains, so I ordered him the squill mixture I gave the first patient, with twenty minims of tincture of henbane every six hours. But bearing in mind his gouty tendencies I added a pill at night of colchicum and Dover's powder as before.

He soon improved greatly as regards the cough, and the expectoration diminished, and became opaque, and of a bluish colour, but the subsidence of the bronchial affection was again simultaneous with the development of gout, though of a less acute character than on the last occasion, this difference being possibly due to the specific treatment the patient had been undergoing before its appearance. In addition to the night pill he again took the iodide of potassium, carbonate of ammonia, and colchicum wine, and soon ceased to be treated, being quite free from both gout and bronchitis.

Time will not allow me, even if I wished, to bring forward cases showing the true relation which I believe to exist between bronchitis, on the one hand, and gout, eczema, or psoriasis or gravel on the other. All these different maladies evidently depend upon a common humoral dyscrasia, which in one case produces gout, in another gravel, in a third psoriasis, or, as in this last case, bronchitis, coexisting or alternating with one or more of these other ailments. These cases are all therefore examples of what I have called secondary bronchitis—that is to say, bronchitis arising out of some

internal condition of the system, that internal condition being, as we have seen, the existence of the humoral dyscrasia, which is known as the cause of gout.

Regarding the treatment of this form of secondary bronchitis, it is clear from the necessarily complicated nature of the subject that I cannot pretend to give any specific directions. The remedies appropriate to the bronchitis and to the other affections must obviously be varied and modified from time to time, in order to meet the constantly varying condition of different patients, and of the same patient at different times. The one essential point towards the successful treatment of all such cases is that we should constantly bear in mind the presence of a constitutional cause for the local affection, and not rest satisfied with directing our efforts towards the removal or alleviation of the bronchitis, but endeavour, as far as possible, to combat the dyscrasia, which is the real source of our patient's ailment.

Dr. Wheeler proposed and Dr. Esler seconded that Dr. J. Strafford Smith and Dr. Dickey be members of the Society

W. Whitla
January 22nd 1884

1884. Fourth Meeting of the Society was held upon Tuesday January 22nd.

Present, Professor Dill President in the chair, Drs. Esler, Whitla, McConnell, Dwyer, J. W. Browne, Kevin, O'Connell, J. C. Smyth and Mackenzie, Secretary.

Drs. J. Strafford Smith and Dickey were balloted for and unanimously elected members of the Society.

Dr. McConnell showed a patient the subject of "Jacksonian epilepsy". He stated that the man received a severe blow on the top of his head with a spade in the year 1879. There were 15 pieces of bone exuded from the wound. He had fits which were confined to one side of the body beginning at the tips of the fingers of the affected side from 1879 until 1882 when the fits ceased [?] and until the present time he has had fair health.

An interesting discussion, in which Drs. Esler, Whitla, J. W. Browne, Kevin and the President took part, followed on the advantage of trephining in this case.

Dr. Browne was of opinion that no harm but good would result from the operation as he thought probably the cicatrix was adherent to the dura mater.

Dr. McConnell also showed a patient with chronic eczema of leg which had been healed repeatedly but which as often broke out afresh.

Dr. Esler give notes of "Cases of scarlet fever traceable to milk supply". This paper opened a discussion in which all the members took part.

The Secretary was instructed to procure a copy of

Churchill's "Medical Registrar".

R. F. Dill, President
5th February 1884

Session 1883–84 Fifth Meeting of the Society was held upon February 5th in the Society Rooms Royal Hospital.

Present, Professor Dill President in the chair, Drs. Whitla, Fagan, J. C. Smyth, Lindsay, Dwyer, Strafford Smith.

Dr. Lindsay read notes of a case of remarkable eruption which followed the administration of two doses of iodide of potassium.

All the members present took part in the discussion upon this case.

Dr. Whitla read notes of the case of "chylous ascites" and showed the patient. An animated discussion followed, all the members present expressing great interest in this very exceptional and unique case.

Mr. Fagan's case was postponed until next meeting where he will take precedence of other business.

R. F. Dill, President
26th February 1884

Session 1883–84. The Sixth Meeting of the Society was held upon 26th February in Royal Hospital.

Professor Dill President in the chair, present Professor Gordon, Drs. O'Neill, Esler, Fagan, Whitla, Moore, Dempsey, Dwyer, St. George, Lindsay, McConnell, J. W. Browne, Barron, and Mackenzie, Honorary Secretary. A number of students were present.

Mr. Fagan showed patient (3 weeks after operation) from whom he had removed an exostosis from lower end of femur. The tumour was the size of an orange and was secured in two pieces. Mr. Fagan give a detailed account of the operation. He did not use "Esmarch's band" and he saturated the wound with chloride of lime.

A discussion followed in which a number joined. Dr. O'Neill did not approve of operating without Esmarch band nor did he approve of the use of chloride of zinc after operation.

Drs. Browne and Murray approved of the non-use of Esmarch band in this case and of the free use of chloride of lime.

Mr. Fagan replied in a spirited manner.

Dr. St. George showed a fibrocystic tumour removed from thigh of woman.

Professor Gordon delivered his instructive, original and highly appreciated paper on fractures of the leg.

Paper:¹ DOES a good collection of specimens of fractures of the leg resolve itself into well-defined species? To this I reply most decidedly in the affirmative. Does

¹ [Dublin Journal of Medical Science, 1884, v77, p289.]

each species demand distinct modifications of treatment? To this I also give the same answer. When I consider the frequency of fractures of the leg, and the deformity and lameness too often dependent upon them, I think these results may be attributed to the practice of viewing them in too narrow and restricted a light, assuming that they require for their successful treatment little variations in position and apparatus.

The following are the species and varieties into which the specimens in Queen's College Museum resolve themselves. I have no doubt as the collection increases other forms shall present themselves—of which the present classification is the beginning—of a more extensive and accurate system than that which now prevails, and without which our practice will be empirical rather than scientific.

1. The Articular Fracture of the Upper End of the Tibia.—The obliquity of the femur from without inwards and downwards, and the perpendicular position of the bones of the leg, cause the shock or impulse of the body, in leaping or falling from a height, to impinge chiefly upon the outer articular facet of the tibia; besides, the sharpness of the outer margin of the external condyle of the femur concentrates the force upon the outer part of the outer articular facet, and sometimes drives it into the cancellated tissue of the head of the tibia beneath it. There are three specimens of this accident in the Museum of the Queen's College. In two of them the tibia and fibula are also broken near their middle, presenting examples of the chisel-shaped fracture of both bones of the leg. In one of the two the compact tissue has been driven nearly half an inch into the cancelli of the head of the tibia. The appearance of the knee in this form of fracture would resemble, in a slight degree, genu valgum.

The third specimen shows less depression than the other two, but equally well marked, and not complicated with any other fracture of either of the bones of the leg. I leave it to future observers to give us a more detailed account of this accident, which I believe to be not uncommon.

Treatment—In the first form, where the compact tissue is driven into the cancelli, I do not see how it can be elevated. But in the second variety, where the condyle is broken with fracture of the fibula, we might, by adduction of the leg, separate, to a slight degree, the articular surfaces from each other; and if at the same time the leg were extended, the biceps flexor cruris would be extended, and more or less elevation of the condyle and broken fibula might be attained.

2. Simple Transverse Fracture of the Upper End of the Tibia.—This fracture traverses the upper expanded extremities of the tibia, a little above, through, or a little below the anterior tuberosity. There is no appreciable displacement. The patient is unable to raise the leg in the extended position, but when we grasp and fix the upper end of the tibia with one hand, and with the

other seize the leg above the ankle and move it from side to side, distinct motion between the fragments, with slight crepitus, will be easily recognised; but all doubts will be removed when we make pressure along the line of fracture, acute pricking pain will be complained of, caused by the very minute spicula wounding the soft parts, especially under the tendons of the gracilis and sartorius muscles.

Treatment.—As there is little or no tendency to displacement, all that is requisite to do is to keep the extremity in the extended position and apply a well-padded splint on each side of the limb, extending from the foot to the middle of the thigh, well secured by straps and buckles.

3. Oblique Fracture of the Tibia from before upwards and backwards.—This fracture is often compound, and is usually caused by great force applied to the crista. When the fracture is high up, the lower end of the upper fragment projects very much forwards, while the upper end of the lower fragment is displaced backwards. The fibula is usually broken opposite the seat of fracture in the tibia. In one instance the fibula was dislocated.

Treatment.—If we place the limb in the extended position, the deformity persists, and the more we extend or pull the worse it becomes. If we place it on its outer side, and attempt to relax the muscles by flexion, muscular spasm supervenes, aggravating very much the deformity. If, on the other hand, the heel splint, suitably padded, be applied to the back of the leg, and the limb slowly and gently raised until the thigh forms nearly a right angle with the pelvis, and the leg a right angle with the thigh, the deformity will generally disappear; then placing a thick pad along the anterior border of the upper fragment and dorsum of the foot, we apply the front splint, and, to prevent rotation or lateral motion, a Cline's splint well padded on each side of the limb.

Sometimes, notwithstanding the relaxation of the muscles consequent upon this position, the lower end of the upper fragment still projects forwards. Now the question will arise: What is the cause of this projection? Is it the quadriceps extensor cruris which pulls the fragments forwards, or the upper end of the lower fragment tilting it forwards? If the projection be from the action of the gastrocnemius and soleus acting on the lower fragment, then the flexion of the leg upon the thigh must be increased, whilst upon the other hand, if it be from the quadriceps extensor, the leg must be more raised, and the angle of the thigh with the pelvis diminished until the extremity assumes the position adopted for fractured patella.

When the seat of fracture is lower, approaching the middle of the bone, the padding applied to the back of the leg must be full, whilst that in front should extend only to the lower end of the upper fragment. A small pad must also be applied to the dorsum of the foot. By

this arrangement of the pads, there is a space between the lower fragment and the back of the anterior splint, and there is therefore no impediment to the lower fragment being pressed forward.

4. Oblique Fracture of the Tibia from before downwards and backwards.—In this fracture, which is generally about the middle of the tibia, the sharp end of the lower fragment often protrudes through the integument, the foot is carried backwards, bringing with it the contiguous part of the lower fragment, and causing its upper end to project very much forwards. The fibula is generally broken at or near the seat of fracture in the tibia.

Treatment—When the upper end of the lower fragment protrudes through the integument the patient is to be placed upon the back, the thigh flexed very much upon the pelvis, and the leg upon the thigh; then an assistant seizes the upper portion of the leg, whilst the surgeon grasps the foot and lower part of the limb, and makes extension downwards and backwards; then, on slowly raising the heel, the deformity will disappear. The heel splint, well padded below, is applied to the back of the leg; then a pad in front, extending over the dorsum of the foot and entire length of the tibia, is laid along the crista, and over this is placed the anterior splint; then a Cline's splint, well padded, is applied to each side of the limb, to prevent lateral displacement, and the whole secured by straps and buckles, or a bandage, and the limb placed upon the "rest," or a MacIntyre's splint, with the leg-piece elevated. Salter's apparatus, as usually made, does not allow of sufficient elevation, and, therefore, does not give us the relaxation of the posterior muscles of the leg requisite to the apposition of the fragments. It is in this form that the sharp angular end of the lower fragment is found to have burst through the skin, which, closing around it, prevents reduction.

The practice to be followed, I think, should depend upon the acuteness of the fracture. If it be narrow and long, we may saw it off, and then, raising the heel, it will slip into its place; or it may be necessary to pass a director into the wound, elevate the integument, so as to draw it over the projecting point. If the projecting end be of considerable thickness, it will be better to enlarge the wound in the skin. After this we cover the wound with a piece of lint, saturated in the compound tincture of benzoin, and apply the splints as before mentioned.

5. Fracture of the Tibia, with displacement of a large central fragment—I saw lately an instance of this form of fracture, the result of a railway accident. The seat opposite to that upon which the patient had been sitting at the time of collision striking the leg, forced from the middle of the tibia backwards a large triangular fragment. It was in the eighth week after the accident when I first saw him. This triangular fragment was quite movable, and displaced considerably back-

wards and slightly inwards. The upper and lower portions of the tibia were approximated, causing considerable shortening of the limb; the latter, at its lower end, was inclined considerably inwards, while its upper end pointed outwards. The impediment to the replacement of the middle fragment was the approximation of the upper and lower pieces of the tibia.

Treatment—The limb had been slightly raised, and two Cline's splints had been applied, with pads on each side. To allow of the return of the displaced fragments, it was necessary to raise the leg much higher, in order to produce greater muscular relaxation. Flexing it upon the thigh, and the thigh upon the pelvis, the heel splint, well padded, was applied posteriorly; a small, soft pad was placed over the triangular or middle fragment, and a thick one along the inner side of the foot and ankle, and a Cline's splint applied to the leg on its outer and inner surfaces. The effect of this change in the position of the limb in a few days became apparent, as the middle fragment had nearly resumed its proper position, and after this the case progressed most favourably; and, considering the serious character of the injury, the patient has recovered with a very useful limb, with scarcely any deformity or lameness.

The case may be regarded as the type of this form of accident, and its treatment cannot be successful unless the muscles are relaxed to their utmost, to enable us to make room for the displaced middle fragment.

6. Simple Transverse Fracture of both Tibia and Fibula at the junction of the Lower Third with the Upper Two-thirds.—Is a comparatively rare accident, and is caused by direct violence, applied transversely, breaking both bones on the same plane. There is no vertical displacement, and the deformity which results is displacement backwards of both fragments. The tibia and fibula are sometimes soldered together; at other times they are not so, but the interosseous space is diminished, with a narrowing of the transverse breadth of the leg at the seat of fracture.

Treatment—In the treatment of this fracture the heel, or posterior splint, must be well padded at the seat of fracture. The front pad should be thick over the lower end of the tibia. The limb may be placed in the straight position, and when the anterior splint is applied and the straps tightened it will act chiefly upon the lower end of the lower fragment, and push it backwards. In this, as in the spiroid fracture, we must be on our guard not to allow the lower fragment to rotate on its vertical axis. For this purpose we must apply a Cline's splint on the outer side of the limb, the foot-piece being well padded to prevent this rotation.

In two well-marked specimens of this accident, in the Queen's College Museum, inclination of the fragments backwards has produced a very great convexity behind, or concavity in front, which becomes remarkably apparent when we stand and look horizontally across the limb; and more than this, as the weight of the

body is thrown on the posterior part of the articular surface of the tibia, and the astragalus, a chronic arthritis and osteitis supervenes. This is a very good example of the mischief which results, unperceived by the surgeon, until too late, by treating the accident with a Cline's splint on each side, or by the use of a starch bandage. By the former there is no support behind, and both fragments gravitate backwards; and by the latter, from the looseness caused by the shrinking of the limb, and the weight upon the heel, a similar deformity results. And, moreover, it presents us with another instance of chronic osteitis, supervening when the natural bearing of the joint surfaces upon each other is altered, and leading to a chronic inflammation which persists, entailing lameness for a long time after the accident.

If the limb be placed on the "double-inclined plane," and steadied by two Cline's splints, the heel will gravitate backwards, carrying with it the lower end of the tibia, and producing an unusual prominence of the upper end of the lower fragment in front. And this remark is applicable not only to this, but to other forms of fracture of the leg, which tend to gravitate backwards from want of adequate support to the heel.

7. The Chisel-shaped Fracture of the Tibia.—This is by far the most common of all the fractures of the leg, equalling in number almost all the other fractures conjoined. It is caused by force being applied from without inwards. The patient in walking sets the outer side of his foot upon a stone. The outer side of the foot being thus elevated, the inner side is depressed, and the weight of the body being suddenly thrown obliquely across the tibia, it breaks obliquely from without inwards and downwards, the fibula, giving way sometimes opposite, but most frequently close to the head. On examination, the lower end of the upper fragment may be felt somewhat rounded, with a little projection in its middle, and the displacement seems slight, but it is always much greater than it appears.

As the upper end of the lower fragment is displaced outwards, the change which the lower or articular end undergoes deserves more consideration than has been accorded to it. The articular surface becomes more oblique with elevation of the internal malleolus, and the foot following the articular surface, its inner border is more raised, and most of the patients who have received this accident walk afterwards more on the outer side of the foot than usual.

Treatment.—Of all the fractures of the leg, the following mode of treatment is that which I found followed by the most satisfactory results:—Observing that the inner malleolus was raised, in order to bring it downwards to its natural position, two conditions were necessary—the first was to relax the muscles; the second was to powerfully abduct the foot; and to enable me to do so I had a splint constructed, to which I have given the name of the "double-bevelled splint." It is

made of a piece of pine, about an inch in thickness, and of the general form of Cline's splint. The foot-piece is cut off obliquely, so as to allow of abduction of the foot. Placing a thick pad on the leg portion of the splint, the limb resting on its outer side is placed upon it, then grasping the upper end of the leg with the one hand, whilst with the other seizing the foot and foot-pieces of the splint, and gently flexing the leg upon the thigh, at the same time abducting the foot, it will almost uniformly be found that in the act of flexion the bones drop accurately into position—so accurately, that it is even difficult to detect where the limb is broken. Then apply the front and back splints, secured by straps and buckles. The patient is to be kept lying upon his side, with the leg flexed upon the thigh, and the thigh flexed upon the pelvis. Some patients dislike the side position, and will complain against it; but if the surgeon be resolute, in a few days they will become reconciled to it.

I have a cast of a fracture of this variety, in which the tibia is broken an inch above the inner malleolus, with fracture of the fibula, two inches from the lower end, with displacement of the malleolus outwards, consequently with great increase of the inter-malleolar space. Where the fibula is broken so low down, and displaced as described, the abduction of the foot would be injurious; it, therefore, must be kept straight, and with this exception treated as previously described.

There is also another specimen of this accident, in which the foot is so much turned inwards that the patient walked on the outer part of its upper surface, as if he had been suffering from talipes varus.

8. Spiroid Fracture of the Tibia.—This fracture occurs in the middle third, or rather in the lower end of the middle third of the tibia, and is usually caused by force applied to the inner surface of the tibia whilst unsupported, except at its extremities. The lower end of the upper fragment presents internally an elongated spire, which, being driven into the upper end of the lower fragment, splits it obliquely downwards, the fissure extending into the articular surface. The upper end of the lower fragment behind presents also an elongated spire, less acute, however, than the internal. The sides of the inner spire are cut vertically to the surface, whilst the spire of the lower fragment is divided obliquely, showing in the clearest manner that the osseous fibres of the compact tissue of the internal surface of the tibia have been broken by compression, whilst those behind, or externally from their obliquity, have given way by elongation.

Diagnosis.—The diagnosis of this accident is easily made. The elongated spire of the upper fragment projects the integument so prominently that it can be easily seen and felt, and the crista of the tibia is also remarkably prominent, notwithstanding the great effusion of blood which takes place immediately after the accident.

Treatment—Those surgeons who have written on this

accident regard it as one which will often require amputation. From the few examples I have seen of it, the treatment will be as successful as any other fracture of the leg, and with as little deformity. Take the heel splint, pad it well, especially opposite the seat of fracture, then raise the limb, supported by the splint, until the thigh forms a right angle with the pelvis, and the leg a right angle with the thigh, and whilst the assistant holds the leg in this position, the surgeon, seizing the foot, makes gentle extension, and at the same time rotates the foot inwards—the fragments then usually drop into their most accurate approximation, all deformity disappearing. Immediately after the accident, from the foot resting upon the heel, and from the action of the tibialis anticus and the extensors of the toes, the lower fragment is rotated outwards.

If extension be made with the outward rotation maintained, it will be of no use; the fragments will not go into position. It is absolutely necessary, then, while we extend to rotate inwards. If we place the limb in the extended position the fragments will not go into their place; and, even should we succeed in the reduction, on the following day the deformity will have reappeared.

The way to treat this accident is to take the heel splint, well padded, raise the limb, flex the thigh upon the pelvis, and the leg upon the thigh, and having corrected the deformity by extension and rotation of the foot inwards, place a Cline's splint on the outer and another on the inner side, with a front splint, all suitably padded, and made firm with straps and buckles. This position must be maintained for four or five weeks by placing the limb upon a box, a "double-inclined plane" with the foot-piece elevated, or a leg—"rest."

Special care must be taken to place a thick pad between the foot-piece of the outer Cline's splint and outer margin of the foot, to maintain the rotation inwards of the foot. The limb may also be placed flexed in the same manner resting on its outer surface, but the leg must be well flexed on the thigh.

The explanation of the great fatality of this accident is mainly due to two causes, viz.:(1). The sharpened end of the upper fragment often bursts through the skin, making the fracture compound, or subsequently making its way through the integument by ulceration. (2). The spire of the lower fragment, which is usually very sharp, wounds the vessels behind, and great effusion of blood takes place, injecting the limb; and if we add to this the inflammatory products and putrefaction of the effused blood, we can then easily see why the accident should be so frequently fatal. Now, however, the antiseptic mode of treatment may have some influence in counteracting such disastrous results.

9. The Bread-cart Fracture.—I have given this name to a not uncommon accident in which a person is thrown down by a bread-cart, jaunting-car, or other vehicle running quickly.

The patient being thrown on his side, the wheel passes

over the inner surface of the leg. If it be at the ankle-joint, both malleoli will be found to be broken off, and the lower end of the tibia crushed and comminuted. If it be higher up, at the junction of the lower with the two upper thirds, the compact tissue of the inner surface will be broken into lozenge-shaped fragments, and driven into the medulla, and also displaced outwards, with fracture of the fibula, at the point where the wheel passes over the limb, the inner malleolus being elevated. If the wheel has passed higher up, the inner surface of the compact tissue will present numerous elongated spicula, whilst the angles, which are the strongest portions of the bone, will be broken off, and present themselves as long detached fragments. A moment's reflection will show us that this is a most serious accident, although there may be no external wound; for the long sharp fragments are driven into the medulla, which will lead to inflammatory action ending in death of many of the loose spicula; therefore, the fact of a wheel passing over the limb as described, although the injury and deformity may seem at first sight trifling, should lead the surgeon to give a very guarded prognosis, as the inflammation, suppuration, and necrosis will sooner or later necessitate amputation.

Treatment.—The limb should be placed resting upon its outer side, with the thigh flexed upon the pelvis, and the leg upon the thigh, with the foot abducted, and the inclination of the fragments either forwards or backwards should be prevented by the anterior and posterior splints.

10. Fracture of both Malleoli on the same plane as the inferior surface of the Tibia.—Both malleoli may be broken off with various forms of severe fractures of the leg, but, in the accident to which I have given this name, the injury is confined to the fracture of the malleoli, and it is caused by (1) forced extension of the foot with the leg more or less fixed, or (2) by forcible extension of the leg with the foot fixed. The accident may be regarded as the first stage of dislocation of both bones of the leg forwards or of the foot backwards.

Diagnosis.—The diagnosis is very easy, as the heel is carried backwards and upwards, whilst in front the lower end of the tibia projects slightly forwards. Both malleoli may be felt movable with slight crepitus; and as the processes follow the foot backwards, a small space in front may be felt between the inner malleolus and the tibia.

Treatment—Apply the heel splint well padded below, then the front splint with a thick pad over the lower end of the tibia, a Cline's splint on each side, thickly padded, over the malleoli, so as to press them firmly against the articular surface of the astragalus. The heel splint pushes the foot forwards, whilst the front splint presses the tibia backwards, and the Cline's splint fixes the foot, preventing any lateral deviation of the fragments, as either abduction or adduction would act injuriously by displacing the fragments. The leg may be

placed in the extended position—if so, it may be requisite to have the straps, which bind the splints together just above the ankle-joint, very tightly buckled, to prevent the heel from going backwards; however, if there be the slightest tendency to projection of the heel backwards, then the leg should be placed upon the “rest” in a semi-flexed position. Dislocation of both bones of the leg forwards is to be treated in precisely the same way, but the semi-flexed position should be adopted from the beginning.

11. Potts' Fracture.—There may be some difference of opinion as to what is meant by Potts' fracture. I, therefore, restrict the term to that not uncommon form of accident in which the inner malleolus is broken off with fracture of the fibula from one and a half to two and a half inches above the lower end of the outer malleolus. In whatever position the patient may be lying when we see this accident, the foot is usually abducted and displaced outwards, with its inner border depressed, and the heel carried usually more or less backwards.

Diagnosis.—The diagnosis is very easy. The inner malleolus may be felt to be movable, and the border of the tibia from which it has been detached may be distinctly felt.

On the outside the outer malleolus will be pressed outwards by the displaced foot, whilst the upper end of the lower fragment will be carried inwards and often forwards, producing a diminished transverse breadth of the leg at this point, with increased lateral diameter lower down, at the point of the malleoli. As this accident is caused by twisting of the foot outwards, or by forcible abduction, we may consider as different degrees of the same accident—(1) Simple Fracture of the Fibula, from one and a half to two and a half inches from its lower end; (2) Potts Fracture; and (3) Dislocation of the Tibia inwards, or the foot outwards—the simple fracture of the fibula being its mildest form, Potts' fracture being the more severe, and the dislocation of the tibia inwards the most severe form. This classification or arrangement of the subject will simplify matters, as the principles of treatment are the same in each. In simple fracture of the fibula the heel is usually displaced backwards, with widening of the inter-malleolar spaces.

Treatment.—Various modes of treatment have from time to time been recommended, but whatever mode be adopted, the heel must be pressed forward and the foot adducted.

By Dupuytren's mode of treatment, or placing a thick pad extending along the inner side of the tibia to the malleolus, with a wooden splint extending beyond the foot, it will maintain the foot sufficiently adducted to correct the deformity caused by abduction; but it does not act sufficiently on the heel to bring it forwards and restore the fibula to its natural position.

The tibio-fibular articulation is the centre of the move-

ments in these accidents—thus, when the heel is carried backwards, the lower end of the lower fragment is carried backwards, while its upper end projects forwards; and in addition to the lower end being displaced outwards by the abducted foot, the inter-malleolar space is increased, with diminution of the transverse breadth of the interosseous space at the seat of fracture. In the treatment of fractures of the fibula no pressure should be made on any part of the shaft of the bone between the points at which it rests against the tibia; hence, in the treatment by Cline's splint along the outer side of the limb, one pad should be applied over the outer malleolus and outer surface of the foot, whilst the upper pad should rest upon the head of the fibula and above it, so that the whole length of the body of the fibula will be free and uncompressed.

If the upper end of the lower fragment projects forwards, then it becomes necessary to use some appliance to push and maintain the heel well forwards. The heel splint will do this. It is necessary to apply an anterior splint to enable us to act upon the posterior splint. Then place the limb on its outer side, with a pad on its outer margin, so that when the limb is placed on its outer side the foot shall be well adducted. Care should also be taken that in Potts' fracture and in dislocation inwards, where the inner malleolus has been broken off, the outer margin of the foot should be well raised; for if the foot be allowed to rotate outwards, the inner malleolus will also be unnaturally rotated.

From the description now given of the treatment of fractures of the leg followed by me, it resolves itself into the use of apparatus of the most simple kind—the heel splint, the front splint, two Cline's splints, and a double-bevelled splint, which permits of the fullest abduction of the foot.

Next, the position in which the limb is to be placed—first, in the straight or extended position, which is applicable only to a few cases, and it may be confined to those cases in which, from their nature, vertical overriding is impossible; secondly, where the patient lies on his back, the thigh flexed almost to a right angle on the pelvis, and the leg upon the thigh; thirdly, those in which the patient lies upon his side, with the leg well flexed upon the thigh, and the foot either abducted or adducted.

I have used the term “rest,” and this name is given to an apparatus which consists of four upright posts made of iron, which support a platform either end of which can be elevated or depressed, and which admits of the leg being placed upon it with very slight extension, or of being at either a right or acute angle with the thigh, giving us all the muscular relaxation necessary to enable us to counteract overriding of the fragments.

I have no faith in the prevention of overriding by forcible extension. Where I have tried it I have failed, but when my attention was directed so as to produce the most perfect muscular relaxation, I do not remem-

ber an instance in which it failed.

All displacements—forwards, inwards, backwards, or outwards—may be easily prevented by the four splints—the front, heel, and two Cline's splints—and then placing the limb in a position in which the muscles are relaxed.

There is another point which, as regards position, must be carefully observed by the surgeon—namely, if the fracture be oblique from before backwards and upwards, or from above downwards and backwards, the patient must lie on his back; for if he be placed on his side lateral deviation of the fragments will take place, and muscular spasm will be the result. If the fracture be oblique from without inwards and downwards, then the limb must be placed on its outer side, with flexion of the leg upon the thigh, and the thigh upon the pelvis.

To make my meaning more easily understood, placing the one hand upon the top of the other, the flat surfaces must look upwards and downwards. That is the position in which the fracture must be treated. Turn the hands so that the edges will be vertical, then it will be seen how easily the ends of the fragments will become displaced.

The President and Dr. Esler congratulated the Society on the honour conferred upon it by Professor Gordon.

Alexander Gordon
March 18th

Session 1883–84. The Seventh Meeting of the Society was held upon Tuesday 18th March in the Royal Hospital.

Present, Dr. Whitla V.P. (occupied the chair), Professor Gordon, Drs. Lindsay, Barron, O'Neill, J. W. Browne, St. George, Wales, and Mackenzie, Honorary Secretary. A number of students were present.

Dr. O'Neill read a paper on "Fractures of the patella" and showed a patient the subject of the accident and illustrated his mode of treatment.

Professor Gordon mentioned cases in which osseous union had taken place in fracture of patella. To ensure this there must be perfect apposition and the failure to secure this accounted for the rarity of true osseous union.

He approved of wiring the fragments and using a back splint to prevent flexion of the knee joint. He thought that in many cases both direct violence and muscular strain were at work in producing the fracture.

Dr. J. W. Browne did not approve of wiring the fragments. He spoke highly of Spence's method of treatment by a modification of Malgaigne's hooks.

He did not approve of any pressure about the joint lest it might interfere with the articular arteries. He thought it well to aspirate the joint if there was evi-

dence that an effusion of blood had taken place.

The chairman concluded the discussion and Dr. O'Neill replied.

Mr. Fagan's case was postponed owing to the advanced hour.

The Chairman read communication from the telephone company. It was agreed to take no action in the matter.

R. F. Dill, President
April 1st 1884

Session 1883–84. Eighth Meeting of the Society was held in the Royal Hospital upon Tuesday 1st April.

Present, Professor Dill, President in the chair, Drs. Moore, Esler, McFarland, O'Connell, McKee (visitor), James Smith, J. C. Smyth, and Mackenzie, Honorary Secretary.

Dr. James Smith read a paper on cephalotripsy and exhibited his own cephalotribe placed on the head of a child which he and Professor Dill had delivered a few days ago.

Paper:¹ THE following are the chief peculiarities of the cephalotribe I show:—

1. It is longer than those in use, being 15 inches, of which the blades are 10 and the handles 5, therefore better adapted for operations at or above the pelvic brim. Each blade and handle is measured from the lock respectively.²

2. In breadth of blade and pelvic curve this cephalotribe is similar to Barnes' long forceps—an instrument I have used upwards of six hundred times in 4,000 deliveries. I have therefore modelled my cephalotribe on the lines of a forceps whose efficiency I have fully proved. Further, as I believe axis-traction depends more on the accoucheur than his tool, I discard all useless encumbrances, such as traction rods with the accompanying belly-band or waist belt.

3. The cephalotribe possesses also a very moderate cephalic curve; this facilitates introduction, and combined with the pelvic curve renders slipping less likely when the head occupies a very anterior position above the pubes. Here straight cephalotribes fail.

4. This cephalotribe is much less formidable and more efficient than those of Hicks, Kidd, &c., and can be applied in the same manner and with as great facility as the ordinary obstetric forceps. The services of an assistant are optional.

5. When the screw is applied to its utmost limit the space occupied by the blades is one inch and a half.

6. The shoulders, in addition to affording greater tractile power, facilitate rotation. They should be of a piece with the handles, and not "dovetailed" therein.

7. The fenestræ yield the following advantages (a.)

¹ [Dublin Journal of Medical Science, 1884, v77, p472.]

² The free borders of the grooves look towards the lock, and not towards the apices of the blades, which might be inferred from the woodcut.

They add to the lightness of the cephalotribe. (b) As compression goes on the head bulges through (almost to a level with the outer surfaces of the blades), and enables the instrument to hold with much greater tenacity, (c.) For the same reason expansion is obviated to a great extent in one direction, while compression is going on in another.

8. The grooves prevent slipping also, but these might perhaps be dispensed with if the instrument were used only as a cephalotribe; but its employment as a craniotomy forceps in some cases of extreme pelvic distortion, and more especially in those cases where mal-presentation of the foetal head coexists with maternal deformity (e.g., the face with approximation of the tubera ischii), the instrument has proved vastly superior to the craniotomy implements hitherto in use, and has, in the opinion of the leading accoucheurs of the North of Ireland, superseded them entirely. The grooves are, in my opinion, indispensable to the efficiency of the instrument as a combined cephalotribe and craniotomy forceps.

9. The weight of the cephalotribe is about 2½ lbs. The ponderosity of the instrument is considerably augmented by the somewhat heavy but withal neat handles. However, obstetrically speaking, I am a believer in weight—indeed I cherish the conviction that the maternity physician—to be an efficient one—should overbalance twelve stones, while the occupant of the “Master’s Chair” should counterpoise at least sixteen.

10. The practical utility of this cephalotribe is best proved by the fact that it has been successfully used during the past seven years in upwards of thirty instances, some of course being repetitions on the same patient, but the record of one case will illustrate all. Here follow the particulars of a case I narrated to the meeting of the North of Ireland Branch of the British Medical Association, January 17, 1879. On that occasion I not only showed my depopulating tool, but I exhibited its foetal victim. The child weighed at time of birth 8¼ lbs., and was extracted from a woman on whom the operation of craniotomy had been twice performed by Professor Dill and others. On the last occasion the exostosis on the sacral promontory had progressed to such an extent as to preclude the application of Barnes’ long forceps in any diameter. My cephalotribe was applied by Professor Dill and myself, and delivery was accomplished with ease and safety in almost as many minutes as the previous confinements

occupied hours. Recourse was not had to the perforator or other instrument. Let me now apply myself more directly to the business in hand—namely, to show the utility of this cephalotribe as a craniotomy forceps. After more than five years’ rest, during which the pelvic deformity had much increased, this interesting patient again became pregnant, and in the fulness of time sought our professional services.

The facts are briefly as follow:—On the forenoon of Monday, March 24th, of the present year, I was hastily summoned to the parturient couch of this distorted female, and on vaginal examination I detected the right hand presenting through a somewhat rigid os of the size of half-a-crown. Anticipating Professor Dill’s arrival, I introduced per rectum a suppository containing ½ gr. mur. morph. and gr. i. ext. belladonna. This medicament soothed the patient and softened her os. About an hour after the introduction of the suppository Dr. Dill arrived, examined the patient, and found the right hand in the vagina and the os tolerably well dilated and dilatable. We determined on immediate action, and the patient having been chloroformed by Professor Dill, I proceeded to deliver by podalic version. At first I grasped both feet, but on coming to the obstruction I had to relinquish one, the right, but I succeeded in retaining the left in custody until it cleared the vulva.

Traction was now made on the liberated limb, and after the employment of much force the breech appeared, soon followed by the rest of the body, including the arms. At this stage Professor Dill and I conjointly manipulated the body, so as to release the after-coming head, but our efforts were unavailing. The last act of the tragedy consisted in the reduction of the head by the perforator and its extraction by means of the cephalotribe. The administration of chloroform and the accomplishment of delivery occupied only fifteen minutes. The patient made a rapid and complete recovery, resuming her domestic duties within a week after the operation.

Professor Dill stated that in this case the head was tilted forward and resting on the pubes where Kidd’s cephalotribe would not catch hold and this fact suggested the shape of Dr. Smith’s cephalotribe. “I have used it for 5 years and have no hesitation in stating that there is no instrument to be compared to Dr. Smith’s modified cephalotribe from the days of Chamberlain to this date and I have had frequent opportunities of using the cephalotribe of other men such as Lusk’s which I [?] and I emphatically say that it is not to be compared to Smith’s.”

Professor Dill showed a full-grown child which he had a few hours previously delivered by Smith’s cephalotribe. The child was hydrocephalic and had spina bifida.

Drs. McFarland, Esler and Moore congratulated Dr.

Smith on his useful instrument.

Dr. Mackenzie mentioned a case in which he perforated and used Simpson's cephalotribe but he should have preferred using Smith's.

Dr. Smith replied and thanked the members present for their kind criticisms on his paper and cephalotribe.

*Discussion on the New Cephalotribe.*¹

THE PRESIDENT said—Since the invention of the forceps by the Chamberlaynes, now upwards of two hundred years ago, I am of the opinion we have not had furnished to us an instrument equal to Dr. Smith's cephalotribe, suited as it is so well to certain very difficult cases of labour.

I can now exhibit Lusk's modified cephalotribe, so that you can at once have an opportunity of seeing and comparing for yourselves the two instruments, and having done so, I think you will agree with me (who have had considerable experience in the use of each) in deciding in favour of the greater advantages afforded in the use of Dr. Smith's cephalotribe.

I remember well the painful peculiarities of the case which first suggested to Dr. Smith and myself the necessity for such a design as is to be seen here in his instrument.

The case was one in which we found a narrow pelvis, the head above the brim, forward, and somewhat resting upon the pubic bones. After having perforated we made more than one attempt to get Kidd's cephalotribe over the head so as to seize it properly, but without success, for as it was too much forward and outside the line or axis of the instrument the head could not be properly reached. We had, therefore, no alternative but to fall back upon the crotchet and such other means as we had at our disposal, and after nearly three hours of much anxious work we succeeded in bringing away a foetus of more than average size.

The patient made a good and quick recovery, and she became pregnant soon again. In the meantime Dr. Smith had given such instructions to a manufacturer regarding the design and make of his instrument as were suggested by the peculiar characteristics of the case just brought under notice, and the instrument was in our hands before her next confinement.

We met again at the bedside of this difficult, but interesting case of labour. We were, however, somewhat fortified by being in possession of what we believed would meet the emergency, though a little anxious, as the instrument was about to be put upon its trial for the first time; but I am free to say that it more than realised our hopeful expectations, for the perforation, the application of the instrument, and bringing the operation to a successful termination did not occupy much over as many minutes as our first occupied in

hours.

Dr. Smith has just narrated the history of the case, and the operation which he and I performed for the third time upon the same patient with his new and improved cephalotribe, and which served our purpose even better and easier than did his first instrument; and it is now so admirably finished and complete that I think the time is very remote when any material alteration in it may be considered necessary.

Following up the same subject, I may now be allowed to exhibit a large sized foetus, hydrocephalic and with spina bifida, which I (in company with Dr. M'Kee, whom I am glad to see present) brought through the narrow pelvis of a little and a deformed woman, and this even in a very short time and with comparative ease, by means of Dr. Smith's cephalotribe.

I have now used this instrument during the last five years both in town and country in very many cases, and with the greatest satisfaction, and the gentlemen with whom I was in consultation invariably expressed themselves not only pleased but surprised at the wonderful facility with which the work was accomplished, and the short time and ease with which an otherwise laborious case was brought to a successful issue by means of the instrument now under consideration.

Will you allow me, before bringing these very hasty and imperfect remarks to a close, to direct your attention to a case which I see reported by Dr. Atthill, when in the Rotunda Hospital, and in which case I can recognise similar difficulties as were discovered in the case so often under the care of Dr. Smith and myself, and Dr. Atthill experienced equal inability in the application of the cephalotribe as we had done, and like us he also had to call in the aid of the crotchet. Since that time, I believe, Dr. Atthill has put himself in possession of Dr. Smith's cephalotribe, and I believe it is now a favoured instrument with him.

DR. ESLER and DR. M'FARLAND congratulated Dr. Smith on the production of such a useful and complete instrument.

DR. MOORE was much interested in Dr. Smith's paper. He always felt the great responsibility which rested upon the medical man who decided to perform the operation of cephalotripsy. He did not approve of calling Dr. Smith's cephalotribe a depopulating instrument.

DR. MACKENZIE narrated a case in which, after turning, he was obliged to perforate and deliver with Simpson's cephalotribe, but he thought the use of the cephalotribe exhibited by Dr. Smith would have saved time and trouble. The mother in his case made a rapid recovery.

DR. SMITH thanked the Society for the kind reception accorded to his paper, and for the interest taken by the members in his new and improved cephalotribe.

Moved by the Honorary Secretary and seconded by

¹ [Dublin Journal of Medical Science, 1884, v77, p562.]

Dr. J. C. Smyth that Dr. A. P. B. Moore, M.D. be elected member of the Society.

W. Whitla, Chairman
April 29th 1884

Session 1883–84. Ninth Meeting of the Society was held in Royal Hospital upon the 29th April.

Present, Professor Dill President, Drs. J. W. Browne, Moore, Fagan, Dempsey, Nelson, Barron, Esler, Whitla, and Mackenzie, Honorary Secretary.

Dr. A. P. B. Moore M.D. (Q.U.I.) was unanimously elected a member of the Society.

Mr. Fagan read notes of and exhibited patients upon whom he had operated by excision for enlarged cervical glands. He showed a patient from whom he excised several large glands, the cicatrices being scarcely visible and the results being most satisfactory.

Paper:¹ Excision of scrofulous cervical glands has been a recognised mode of treatment for many years among Continental surgeons, notably by the French school. It has been rather sparingly adopted in this country, and other treatment of a less radical nature is usually practised.

I am glad to see, however, that of late there is a growing disposition on the part of physicians to approve of, and surgeons to carry out, this most excellent method in suitable cases.

My medical colleagues, both at the Royal Hospital and the Children's Hospital, have from time to time brought under my notice, with a view to operation, certain forms of obstinate gland swellings that resisted all the recognised modes of treatment. I have up to the present time operated in about twenty-five cases, and the result in each case has been most satisfactory.

I have on more than one occasion, at this and another Society, shown the patients operated on and glands removed, and to-night I have at random secured two children on whom I operated; one sixteen months, the other a year, ago. In each it is with difficulty that you can detect the seat of the operation wound, its only evidence being an indistinct white streak.

As illustrating my mode of operating, as well as the usual progress and termination of such cases, I will briefly record the features of interest in three or four of them; but before doing so I may be allowed to draw your attention in a passing way to the anatomical arrangement of the cervical lymphatics.

Of these there are two sets—a superficial and a deep one. The first lies along the course of the external jugular vein, beneath the platysma, receiving lymphatics from the skin of the neck, part of the face and scalp, and from the auricle of the ear. The deep chain of glands lying in close contact with the large vessels is divided into a lower and an upper set. The first is situated in

the supra-clavicular fossa, and communicates with the axillary and mediastinal glands as well as with those of the upper set. The latter is placed opposite the division of the common carotid, and receives lymphatics from the tonsils, nasal fossæ, lower part of pharynx, tongue, palate, and larynx, from the deep muscles of the head and neck, and from within the cranium. The sub-maxillary set, placed under the cervical fascia, run along the base of the jaw; they communicate with the superficial and deep cervical sets, and receive lymphatics from the mouth and lower lip. The parotid set—placed some in the substance, others on the surface, of the gland—receive lymphatics from the orbit, nasal fossæ and upper jaw, the upper part of the pharynx, and from the frontal and parietal regions of the scalp.

This brief survey of the principal lymphatic chains in the neck may be of service when considering the local causation of morbid changes in them, as also in carrying out any operative measures for their treatment.

Case I.—My first case was a very healthy-looking little girl, aged eleven years, whose family history was exceptionally good. She had an oval swelling the size of a pigeon's egg, situated on the left side of the neck, corresponding to a point a little above the centre and towards the inner side of the sterno-mastoid. It existed for more than a year, and resisted the ordinary modes of treatment. I decided on removing the gland, and proceeded as follows:—I made an incision immediately over the centre of the tumour corresponding with its long axis, and the fibres of the sterno-mastoid. Holding it between my thumb and forefinger it conveyed the feeling of being very superficial, but on dividing the upper layers of fascia instead of the gland, the fibres of the sterno-mastoid appeared in the wound. It then occurred to me that I had to deal with one of the upper set of the deep cervical chain. So I carefully separated the fibres of the muscle, divided the underlying layer of the deep cervical fascia freely, and exposed the gland placed in close contact with the carotid sheath. I now seized the mass with a small double-tumour hook, and, using gentle traction, drew it towards the surface, while with careful strokes of the scalpel I liberated it from its bed of cellular tissue, thus removing it with comparative ease and very little hæmorrhage. Two smaller glands, placed at either extremity of the large one, I removed in the same cautious manner, after twisting a few small arteries and washing out the wound with a solution of chloride of zinc. I bestowed great care in bringing its edges into accurate apposition by numerous points of very fine silver wire suture.

A bit of protective, a pad of antiseptic gauze, and a bandage, constituted the dressing. On the third day I looked at the wound, and found it healed by direct union. There was neither swelling nor redness nor pain. I removed a few of the sutures and dressed the wound as before. On the fifth day I removed the

¹ [Dublin Journal of Medical Science, 1884, v77, p495.]

remaining sutures and put a pad of cotton-wool over the part. On the day following I showed the child to the members of this Society, when the only evidence of the operation was a scarcely perceptible scar, which I expect through time has become still less perceptible.

The large and one of the small glands on section presented in their centres caseous matter, and one or two small circumscribed abscesses.

Case II.—A. M., aged twenty years, was affected for about a year with a chronic hip arthritis, the result of an injury. His health had been considerably impaired, and for three months prior to operation he suffered from an enlarged gland, situated below the angle of the lower jaw. This commenced as a small, hard lump, which soon became painful, and increased till it attained the size of a small hen-egg. It was treated in the usual way, with iodine application, and cod-liver oil, &c., internally.

When I saw him the mass was mobile, hard, and painless. In operating on this case I made the line of my incision in the long axis of the tumour and parallel with the ramus of the lower jaw. The gland was not so easily turned out of its cellular bed as its mobility led me to expect. The surrounding tissue was somewhat closely matted to it, and there was considerable oozing of blood into the cavity that remained; this was checked by the strong chloride of zinc solution. The wound was sutured and dressed as in the former case. On the second day after the operation I removed the dressings, as he had a rigor and high temperature the previous night. The wound was firmly and evenly united, but there was diffuse inflammation extending from it over the side of the face and neck. I removed most of the sutures, opened up with a probe a small part of the wound at its most dependent angle, passed in a small drainage tube, painted all the surrounding parts with the strong iodine liniment, and put him on large doses of quinine and iron. From that time he improved; there was no discharge, except a little serous oozing from the tube. The wound remained firmly united, and a little inflammatory thickening that was about it at first, soon disappeared.

An interesting feature in connexion with this case is that, notwithstanding the very smart inflammatory action, the new plaster material never gave way, nor did any matter form in the cavity from which the gland was removed.

On section the centre or medullary portion was seen converted into a large abscess cavity, and the cortical portion was much thickened from inflammatory infiltration.

Case III.—J. L., aged nine years, a delicate-looking, badly-nourished lad, the subject of purpura, had an enlarged gland, situated a little below and in front of the angle of the jaw. It existed there for two years, occasionally shrinking, but it never totally disappeared. I removed it in the usual manner, the wound healed by

the first intention, the scar was scarcely perceptible.

On section the centre of the gland presented the characteristic patches of caseous matter, with a few pus loculi.

Among my other cases, while there are few points of further interest, the treatment and its result, as well as the pathological condition of the glands, were somewhat similar to what I have already described. In the case of a young lad, where there were two enlarged glands at the angle of the jaw, one of them was partially necrosed and exposed at the bottom of a ragged ulcer, the other joining it was deeply placed. Owing to the matted condition of the surrounding tissue, I had considerable difficulty in removing them, and in doing so wounded the facial artery. I immediately clamped the vessel on either side of the wound with a Pean's forceps, and after dividing it between secured both ends with catgut ligatures. The case did well. In the case of a reformatory lad, who was an exceedingly unhealthy subject and a most incorrigible patient, the removal of the glands was followed by gaping of the wound and rather profuse suppuration. After a somewhat prolonged convalescence the part healed, leaving a very perceptible scar, but not as unsightly as that which follows Nature's process of suppuration and ulceration.

I show you two strings of glands that I removed a short time ago from a lad's neck (four on each side), two of them as large as small hen-eggs. There was some suppuration, but the case has done well.

This is a case I operated on five days ago; the union is perfect. I keep a very small drainage tube in the dependent angle to drain the cavity, from which I removed one very large and three small glands. (The patient was shown to the members.)

There are a few points connected with the operation and its after-treatment to which I think it worth while to direct your attention:—

1. The incision over the gland should not be made too free; but all the underlying structures should be freely divided from angle to angle of the skin wound. When the gland is well exposed it should be seized with a small tumour hook, and steadily but gently drawn through the wound.

In the majority of the cases that are suitable for this mode of treatment this is a simple process, requiring only the occasional use of the knife, a stout director or the handle of the scalpel being sufficient. When all the affected glands are removed, any ragged shreds of cellular tissue that remain should be clipped away with scissors. All bleeding points should be secured, and the wound well swabbed out with a strong solution of chloride of zinc.

2. Regarding drainage of the wound, I have had good results with and without it; still, on the whole, I think it better and safer to drain either with horsehair or very fine tubes. This is especially requisite in cases where the wound is large, and where there has been

oozing of blood and difficulty of enucleating the gland.

3. As regards suturing the wound, the finest silver wire should be used. It should not be passed too deeply through the lips of the wound, which should be most accurately adjusted, and the sutures should be removed not later than the third day, and sooner if the slightest inflammatory blush should appear at their points of exit from the skin. The marks that follow the suppurating tracks of the sutures are far more disfiguring than the scar from the incision.

4. As regards maintaining the parts at rest while union is taking place, this is most essential for obvious reasons. The most effectual way of securing this is, I find, by means of a night-cap with a pair of strings attached to either side; these are brought down and fastened in front to a thoracic binder, and drawn sufficiently tight to bring the head well forward on the chest. Such a form of restraint is especially necessary in the case of children, who will only remain at rest on compulsion.

5. Should inflammation attack the wound the tension should be at once relieved by removing some, if not all, of the sutures; and if there has been no drainage, a probe should be passed into its cavity at the most dependent angle, and a small tube inserted.

I have now explained to you a certain well-defined mode of treatment, as carried out by me in a considerable number of cases, and I have shown you the results of such treatment. To some it may appear very satisfactory, while to others it may seem an unnecessarily heroic method, subjecting, as it does, the patient to a certain amount of deformity no matter how successfully carried out, and not altogether devoid of risk to the life of the patient.

While deferring a reply on this head, I may be allowed to examine cursorily some interesting features in this broad subject that just now occur to me, as in some way bearing on the mode of treatment advocated in this paper.

In the whole range of medicine and surgery I question if there is a subject concerning which there is more diversity of opinion, regarding both its nature and treatment, than there is about what we term scrofula or struma. The various and conflicting views held at different periods by equally eminent inquirers concerning the nature of this condition; the innumerable nostrums displacing one another in rapid succession—their virtue often consisting in their novelty—is a striking proof of the unstable nature of the basis on which the pathology and therapeutics of this disease rest.

From a purely surgical standpoint I would define the term struma or scrofula as an inflammatory process attacking the tissues of a lowly vitalised organism, and manifesting itself by a slow and silent destructive action.

The exciting causes that are likely to give rise to this condition in the lymphatic glands are many and

obscure:—Traumatism, direct or indirect, through the lymphatics; all sources of irritation, internal as well as external—for instance, bad teeth, sore throat, bronchitis, enteritis, skin affections, exposure to cold, &c. That the glands of the neck are more frequently than any other the subject of this condition will appear evident from the fact that there is a very intimate connexion between them and the large amount of lymphoid tissue in the mouth and pharynx, which in most delicate subjects is highly susceptible to the slightest variation in temperature or the contact of septic matter.

While we know that in almost all cases there are two factors—viz., the hereditary and acquired—in producing the strumous condition, you may ask which plays the more important part?

Mr. Savory, in his remarks on the subject of scrofula, answers this question more fully and satisfactorily than any other author. He says the causes of disease are conveniently and naturally divided into predisposing and exciting, and the development of disease depends on the extent to which these causes act in combination. For example, by way of illustration merely, let it be assumed that any given disease cannot be produced unless the sum of the causes reach a certain figure, say 100. Now, so long as this number can be attained by the causes conjointly, it matters not what their relative share in it may be. The predisposing cause may equal 70, the exciting cause 30, or vice versâ. From this it follows, as is well known, that when the predisposition to disease is strongly marked, the most trivial exciting cause may suffice to develop it—it may be 99 to 1. On the other hand, if the exciting cause or causes be sufficiently intense and prolonged, the disease may be produced where there is only the faintest predisposition.

Let us illustrate this by an example:—Take a child of parents in the better class of life, surrounded by all the necessaries for its wellbeing, and although there may be a strong hereditary tendency, the exciting causes being almost nil, the sum total is not sufficient to develop the scrofulous condition; but suppose that child by some misfortune is reduced to the state that we find the wretched children of the poor in our large cities, the victim of bad air, bad food, uncleanness, insufficient clothing, and particularly in this rough, changeable climate of ours, you will soon see the disease manifesting itself in its most severe form.

The hereditary or predisposing causes among the children of the poor may be almost nil, but the exciting are so many and so forcible that of themselves they often give rise to the scrofulous condition.

The general treatment of this affection in its earliest manifestation, more especially when due to hereditary causes, falls within the province of the physician. But there are some conditions of gland enlargement in which timely surgical interference would be of the greatest possible good. In a healthy subject when a gland enlarges and grows painful, if the tension be not

soon relieved the probabilities are that it will go on to suppuration. The timely relief of tension is a principle I strongly adhere to in dealing with all forms of inflammation, especially when the affected tissues are bound down by a dense, resisting medium. If we consider for a moment the anatomical characters of a lymphatic gland, we shall at once see the necessity there is for attention to this point. When its structure becomes inflamed multiple punctures of the dense, fibrous capsule should be made to relieve the congested gland substance and allow the inflammatory products free exit into the surrounding cellular tissue. It can be practised by means of a fine tenotome passed subcutaneously at some distance from the gland.

I find time will not permit me to discuss the merits of many other useful surgical methods of treating strumous gland disease; and while admitting the thermocautery, Volkmann's spoon, and appropriate caustics to be good in certain forms of the disease, I hold strongly to the opinion that when disease is limited within a well-defined area, and the tissue involved is steadily, however slowly, deteriorating, that its total extirpation is the only rational and effectual mode of dealing with it, and this principle is, I maintain, equally applicable whether the structure implicated be gland, bone, or joint, provided anatomical considerations allow of such operative interference. Let it not be understood that, while making this somewhat strong statement, I am an advocate for the wholesale use of the knife for treating diseased structures. Such a practice I believe to be as mischievous as that where its use is never recommended. But the judicious physician or surgeon who, when he sees diseased structure persistently deteriorating, and not alone so, but endangering the vitality of that in its neighbourhood, recommends its timely removal, is a far greater benefactor to his patients than he who temporises in the hope that Nature, with the aid of his nostrums, will bring about a cure.

Anyone who has seen my cases must, I think, admit that the method of treatment I have adopted is the best for those chronic cases that resist all other recognised remedies. Its superiority over the temporising plan will appear strikingly manifest if we compare a patient restored to health after the rapid riddance of the diseased mass, and showing scarcely any mark, with another graphically described by Dr. Clifford Allbutt as "dragging on a chequered and tedious course, drifting, perhaps, from doctor to doctor, consuming volumes of cod-liver oil and medicines, breaking up life and prospects by prolonged exile from home, pestered by filthy discharges, or poisoned by decay which is not discharged, disfigured by sinuses, sluggish streaks and lumps of fibrous increase, seamy scars, and indurated gland-remnants. Such patients, thanks to the marvellous pertinacity of life, do generally fight their way into complete or partial recovery, but at the price of permanent disfigurement; at the price of tell-tale corruga-

tions in the neck; at the price, perhaps, of a deferred pulmonary phthisis, set up by absorption of the partially voided caseous products."

You will admit that this is not an overdrawn picture, and you will agree with me that scrofula, as it now is, is an opprobrium medicinæ.

An interesting discussion followed in which all the members present took part as to the various methods adopted for the treatment of diseased glands.

Mr. Fagan was congratulated upon the excellent results obtained by excision.

Dr. J. W. Browne showed a patient upon whom he operated for genu valgum by McEwan's method 2 years ago, the result being complete success. The boy before operation was unable to walk, has now two useful strong and straight limbs.

Dr. Whitla showed specimens of chyle. He showed the thoracic duct and the point of obstruction. In 8 weeks he removed 120 pints of chyle from the abdominal cavity. The patient died of tuberculosis meningitis.

R. F. Dill, President, 27th May 1884

1883–84. Tenth Meeting was held in the Royal Hospital upon Tuesday 27th May.

Present, Professor Dill President in the chair, Drs. Browne, Dempsey, McFarland, Nelson, J. C. Smyth, Barron, Kevin, Dwyer, Strafford Smith, Whitla, and Mackenzie.

Dr. Browne read a paper on Paget's disease of the breast. He showed the gland recently removed from a patient in the Royal Hospital.

He also gave notes of a few cases of operation by Bassini's method for the radical cure of reducible inguinal hernia.

The President gave a most interesting and detailed account of a case of placenta prævia to which he was called in consultation 30 miles from town. All the members present expressed their gratitude to the President for very lucid and admirable description given of this very dangerous and difficult case and for the minute details of the practice so successfully carried out by him, so carefully as to save the life that was despaired of by the attending physicians.

Paper:¹ Although the attention of the Society has at different times of late been occupied with the consideration of placenta prævia it may not be altogether unprofitable if we should again pursue the inquiry of that important subject a little further.

I do not now intend to enter upon the discussion of that vexed question—viz., the cause, or the causes, of placenta prævia. I merely mean to advance a few practical hints in relation to the management of a case of this kind, which recently came under my observation,

¹ [Dublin Journal of Medical Science, 1884, v78, p454.]

which is not altogether devoid of interest, and which, I hope, may convey some practical information.

On Sunday morning last I was telegraphed for to see a lady in a distant country town. When I reached the house I found that Mrs. A. B. had been ill in labour from the day before, and that she had been attended to by the three physicians of the place. I was met by one of the medical gentlemen, who told me that this was the lady's fourth pregnancy, that she had lost a large quantity of blood, and that as she was in such an extremely exhausted condition it was almost useless for him to return to the room. I, however, was ushered into the lying-in chamber, where I found the two gentlemen hanging over their patient, doing what best they could, anxiously waiting and watching for the end. I made a hasty examination. The face and the lips were deadly pale, the body was covered with cold perspiration. The pulse at times could not be felt, returning at longer and shorter intervals, but with a very feeble pulsation.

I at once lowered the head and shoulders, elevated the hips, and administered a little brandy and milk. As soon as possible I made a careful vaginal examination, and found there was still some loss of blood going on; the os uteri was about the size of a florin piece, and within was distinctly to be felt the placenta all round, but detached and free at its posterior margin, or sacral side. The os and cervix uteri were more rigid than might have been expected, considering the quantity of blood lost and the patient's extremely exhausted condition. And now, although there was in this case more to be feared than to be hoped, yet we agreed upon a definite and a decided course of treatment, and which in the end proved to be effective and successful.

From the first she was sustained with small, and frequently-repeated, quantities of brandy and milk, and added to this she had every hour, or two hours, either zij. , zi. , or zss. of the liquid extract of ergot. The membranes were at once ruptured. One of Barnes' smaller sized bags was inserted within the os, and it was then inflated by means of an air-pump, and the tampon, formed of handkerchiefs, was carefully introduced until the vagina was completely filled up, and until it projected somewhat from the vulva.

The tampon was now firmly supported by means of a pad, the T and abdominal bandage. Within a couple of hours we saw that our patient was beginning to show symptoms of improvement; the uterus was beginning to contract, as was evident from the recurring pains. At the end of the third hour the tampon and the other appliances were removed. The os had dilated a little further, a bag of a larger size was again inserted, the tampon, pad and bandages were all placed as before. This was done five or six times at intervals of two or three hours, until at last, when withdrawn, it was found that the os had dilated sufficiently to allow the head of a seven months' child to fall through and descend into the pelvis. The foetus was then, with the

slightest assistance, easily brought away, the placenta very soon followed, the uterus gradually contracted, and the case gave us no further grounds for anxiety, as far as hæmorrhage was concerned. From this time the patient went on well, and I was informed afterwards that she made a good recovery.

Allow me now to say that, however interesting the relation of a case of unavoidable hæmorrhage may be considered, it is not on that account, neither is it because of the complete success with which our efforts were crowned, that I bring the subject now before you, but that I may direct your attention to the manner in which the tampon in such cases should be used, if we are to expect any good results from it. To act efficiently, the vagina must be well filled, indeed firmly packed, with the material of which the plug is formed, and until it becomes prominent at the vulva; and as already stated, the pad, T, and abdominal bandage should then be so firmly applied as to produce the necessary amount of pressure.

Thus, with the pressure upon the tampon below, by means of the pad and T bandage, and the pressure which is brought to bear upon the contents of the uterus (the foetus), by means of the abdominal bandage above, you have exerted a force and a counterforce which must, operating and co-operating mechanically upon each other, shut up the mouths of the vessels which lie between the opposing forces so efficiently as to prevent them from pouring out any more blood.

Introduce the plug, as I have occasionally seen it, in a perfunctory manner, it does not serve any good purpose, and it had better be dispensed with altogether; but if introduced promptly and efficiently adjusted, as I have endeavoured to describe the operation, it will be the means of saving many a life.

R. F. Dill, President
17th June 1884

1883–84. Eleventh Meeting 17th of June

Present, Professor Dill President in the chair, Drs. Whitla, Barron, McFarland, J. C. Smyth, Dempsey, Dwyer, O'Connell, and Mackenzie.

Dr. McFarland read his paper on "Cholera with special reference to the treatment by permanganate of potash".

The President related his experience of three epidemics in this country.

Dr. Barron read Dr. Smith's paper on rapid dilatation of the os uteri in placenta prævia.

Paper:¹ Mr. President and Gentlemen, permit me, before proceeding to read the few notes I have written out on the subject of "placenta prævia," or "placental presentations," to offer some apology for again obtruding myself so soon on this Society. Indeed I had no

¹ [Dublin Journal of Medical Science, 1884, v78, p83.]

intention of occupying any of your valuable time on the present occasion, had it not been for the importunities of your energetic Secretary, Dr. MacKenzie, who insisted on my hunting up an obstetric case which might add a little variety, and, perhaps, some interest, to his programme for to-night. Moreover, he intimated to me that this would probably be the last meeting of the Session, and used other persuasive arguments which left me no alternative but to comply—hence my presence here as a contributor this evening. I have chosen this subject (*placenta prævia*) for three reasons—viz., 1st. Because my brief observations may serve as an appendix to Professor Dill's remarks on the same subject made here, I understand, on the last night of meeting. 2nd. Because I was assisted in the case by two members of this Society, who will likely have something to say on the merits or demerits of the operation. 3rd. Because the plan of treatment and mode of delivery differ somewhat from the usual methods. I consider it unnecessary to waste your time discussing the various supposed causes of "*placenta prævia*," or "*placental presentations*," and the endless varieties of treatment and operations recommended in our numerous mid-wifery text-books. Suffice it to say that the causes are not yet manifest, and the treatment, so far, has been attended with great mortality. Statistics at present show a death-rate among mothers of 1 in 3, while 65 per cent, of the children are still-born. These facts prove that there is room for improvement in the treatment of "*placenta prævia*." Having said so much by way of preface, let me now indicate the plan of procedure I have adopted on two occasions, and in each instance to the salvation of both mother and child.

To some people it may seem rather "heroic" treatment, but I am satisfied that the results justify the means, which consist in thrusting the hand through the os uteri at an earlier stage than usually recommended. However, this proceeding looks worse than it really is, for rigidity of the os uteri rarely co-exists with *placenta prævia*. On the contrary, the whole uterus is atonic, soft, and flaccid, and the os participates in the general relaxation; and, when the latter has attained the size of half-a-crown, the hand is forced through it with as little difficulty as through an elastic ring. It will be unnecessary for me to describe the two cases I have referred to, inasmuch as the details of treatment and operation are precisely similar, so that I shall content myself with narrating only one, which is unique in that it presented a contracted pelvic brim as well as the *placental presentation*. This abnormality on the sacrum retarded delivery, but it did not necessitate recourse to any kind of instrumental aid. I now proceed to give you some details regarding this interesting case, which are these:—On the 2nd of April, 1888, I was awoke from my slumbers about 6 a.m., and was informed that Mrs. C. (whom I had attended early the previous year in her first confinement) had had a "dreadful flooding," and

was in a faint or swoon. I dressed myself with expedition, and was promptly at her bedside. I found ample corroboration of the messenger's statement to me in the perilous condition of Mrs. C. On inquiry I learned she was past the eighth month of gestation; that she was bothered through the night with trifling pains. These she attributed to having taken oil. During the night there was no hæmorrhage. It came on suddenly and alarmingly, just immediately before I was summoned.

I now busied myself for the safety of the patient, and the first thing I did was to make a vaginal examination. This revealed a *placenta* through an os into which I could insert my index finger. I do not enter here into the various minor details, such as lowering the head, raising the hips, cooling the room, &c.—all these things are implied, if not expressed; but I plugged after the following fashion, which I think an improvement on Schroeder:—I first introduced, through a large-sized speculum, a sponge saturated with tannic acid glycerine. I then filled the vagina in the manner recommended by Schroeder. Before employing the plug I drew off the urine. After plugging I placed a binder round the patient to compress the presenting part against the plug—this is the chief aim of plugging, and it should never be forgotten. A restorative in the shape of egg-flip was administered, and, the patient having been made comparatively safe, I withdrew. I saw her again at 10 a.m. and 2 p.m., but nothing transpired at either of these visits to call for special notice.

About 5 p.m. Dr. J. C. Smyth had paid me a casual visit, and just as I was mentioning the case to him, and asking his help, a messenger hurriedly came and reported matters worse. We both hastened down, and found the patient blanched and almost pulseless. Restoratives were given, the old plug was removed, and as labour had set in and the os was dilated to the size of a two-and-sixpenny piece, we resorted only to the temporary expedient of plugging with a sponge. Meanwhile we informed the husband (who was related to a medical gentleman in town) of the critical state of his wife, laying stress not only on the immediate danger, but also on the gloomy prospects, and enjoined him to tell his relative that we would be glad of his co-operation and assistance. Our advice was taken, and the medical friend sought, but, being unable to get away himself, he despatched to our aid Dr. Kevin, in whom we found an efficient substitute.

All the necessaries being arranged for the operation, and Dr. Kevin having confirmed our diagnosis as to the presentation of the *placenta*, extent of dilatation of the os uteri, and the pelvic deformity, we proceeded to deliver. The operation was performed thus:—Dr. J. C. Smyth gave chloroform, Dr. Kevin steadied the uterus externally, while I thrust my hand through its os (with as little difficulty and resistance, I repeat, as through an elastic ring) into the uterine cavity, and pulled down the right foot. As Dr. Kevin relaxed his grasp of the

uterus while I was turning, he now resumed pressure, and facilitated the expulsion of the body of the fœtus. All we wanted now was the delivery of the head, which was evidently arrested at the pelvic brim. After a slight pause, during which the child kicked vigorously and the cord pulsated strongly, we made another effort, which was crowned with success. The birth of the child was followed by the immediate expulsion of the placenta, and no hæmorrhage ensued, but as a safeguard we gave a full dose of ergot and firmly encircled the patient with a well-adjusted binder. Both mother and child did well.

In conclusion, I beg to express my obligations to Drs. Kevin and Smyth for the able manner in which they discharged their respective duties, for to their competence and skill I attribute, in a great measure, the success of the operation that I have just endeavoured feebly to depict.

A discussion as to the usual condition of the os in these cases took place. The President wound up the discussion in an able manner, making clear any difficulties suggested by the members.

R. F. Dill President 1st July 1884

1883–84, July 1st. Annual Meeting was held in the Royal Hospital.

Present, Dr. Aicken in the chair, Professor Dill, Drs. Smith (Shankill Road), J. C. Smyth, Dempsey, Kevin, Dickey, Barron, Esler, Wadsworth, J. W. Browne, Harkin, Whitla, Lindsay, and Mackenzie, Honorary Secretary.

The President, Professor Dill, read a most interesting paper on the dilatation of the os and cervix uteri. He showed a number of dilators including Hegar's.

Paper:¹ The subject which is on your notice paper for present consideration, but which has stood over from our last meeting, is possessed of much interest; and although we have been favoured by members of the profession with many contributions towards its elucidation, yet, if I may be allowed to indulge in a little facetiousness, I would say that it may, with some advantage, be further dilated upon. And now, although it scarcely comes within the scope of the discussion of our subject—viz., Dilatations of the Os Uteri and Dilators—yet a few observations regarding the condition and the character of the os and cervix uteri may be here introduced with some advantage before we enter upon the more experimental and practical department of our inquiry. We may, in the first place, assume that the os and cervix uteri are formed of circular and longitudinal muscular fibres, but it is not so easily to be assumed, that while the circular fibres exert a large share in the formation of the os, that they consequently represent a true sphincter muscle. So that if the word sphincter is to be here used at all, it must be but theo-

retically, as the idea of sphincter is not supported by the way in which it acts or dilates.

The os yields and expands slowly and gradually, and in this way its dilatation does not resemble the comparatively sudden response or characteristic relaxation made by a sphincter muscle; for if it were such, should we not have quick labours, as far at least as dilatation of the os uteri is concerned? We cannot afford, therefore, to be so dogmatic as to attribute altogether to muscular contraction the resistance given by the os uteri. Is it not probable, therefore, that it is the mixed condition and character of the tissues of which the os and cervix uteri are formed, composed as they are of not only muscular fibre, but of a firmly condensed connective tissue, binding together the whole structure, which, in this compact condition, offer such a powerfully resisting force as to be merely overcome by the perseveringly repeated efforts of the uterus?

I am inclined to advance this explanation as at least the nearest approach to the truth, and because of the fact that the os uteri at first becomes thinner and thinner, and then it slowly opens. As we find, occasionally, that the os uteri takes a much longer time in dilating than is known to be consistent with the safety of the patient, it has been proposed that artificial means should be instituted towards overcoming this difficulty. This branch of the subject has received the best attention from not a few of our ablest obstetricians, with the result that we are now in possession of a large array of uterine dilators, and those are of different kinds, and forms, and sizes.

The forefinger was at one time very much used, and by many persons it is occasionally used still, for the purpose of assisting to dilate an unyielding os uteri.

The late Sir James Simpson, at an early period in his history, contributed to us his admirable spongent; and in the sea-tangle, *laminaria digitata*, or *tupeto*—which was discovered by Dr. Sloan, of Ayr—we possess an agent much and successfully used as a dilator, and which was at once ingenious and original. But, acting upon the recognised fact that the dilatation of the os and cervix uteri is essentially dependent upon the eccentric pressure exerted by the liquor amnii, Barns discovered an equivalent action and corresponding results from his hydrostatic dilators, or as they are now known and used as air-bags.

There is another class of instruments, with two or more branches or limbs, which move by a spring or hinge; when closed they are introduced into the os and cervix uteri, and, when in, these limbs or branches are separated or expanded with less or more force. To this class belong the dilators of Priestley, Braxton Hicks, Marion Sims, Ellenger, and Brusck.

Another class, which we may here designate as graduated dilators, and which originated with Peaslee, Hanks, and Lawson Tait, are conical in shape, are made of vulcanite, and which are from four to ten in number.

¹ [Dublin Journal of Medical Science, 1884, v78, p175.]

Ulster Medical Society
Session 1883-1884
President Robert Foster Dill

But it is to Hegar's set of graduated dilators that I would now especially direct your attention, though it was not with him that graduated dilators originated, but with Peaslee, Hanks, and Lawson Tait. Hegar's, however, differ from those others both in shape and number, consisting, as his set does, of twenty-six pieces, each piece measuring five inches in length, cylindrical in shape, and having a handle at the end of each, flattened, and an inch and a-half in length. These bougies, as they may be called, are graduated in size, the first being one-eighth of an inch in diameter, and they go on increasing at the rate of about half this size, or one-sixteenth of an inch.

When about to introduce one, the patient should be placed on her left side, and in Marion Sims' position, the under limb brought well toward you and the upper one carried as far forward as possible. The speculum is then introduced, and the cervix should be seized and fixed with a vulsellum, and then one of the dilators is introduced, until it passes through the os and cervix uteri. If it is found to pass freely it may be withdrawn at once and the next larger size introduced. If any difficulty be experienced it may be allowed to remain in ten or fifteen minutes; it may then be withdrawn and the next number can be introduced with ease, and so on, until the parts be dilated sufficiently; and just as we find when the os is opening under natural efforts, so, as the operation proceeds, the dilatation becomes easier and quicker, so that we find it becomes completed in from three to eighteen hours; and as we know the relaxing influence exerted upon the uterus by chloroform, I need scarcely say that if this agent be used the operation is performed with more ease and safety.

If syringing the uterus be the physician's object, he need not go further than the sixth or the seventh piece; if the introduction of nitric acid or other medication be his object, he may require to go as far as the ninth or the tenth; if the finger is to be introduced for exploring purposes, he must go on to the sixteenth or seventeenth; but if his object be the removal of a fibrous or other tumour, he must go on to the higher, probably the highest number. In no cases or conditions do these dilators give more satisfaction or meet the ends more efficiently than in imperfect abortions.

These dilators were introduced to this country from Germany about two years ago by Dr. Macan, of the Rotunda Hospital, Dublin; and from my own experience of them within that time I think I am warranted in saying that they will be found to answer their purpose better than any other instrument or method that has been proposed for the easy and the safe dilatation of the os uteri. However, each instrument possesses certain advantages.

Allow me to add, that smearing over the dilators with carbolic oil will much facilitate their introduction, and by so doing may obviate other grave difficulties. It has been stated that one great advantage in the use of

Hegar's instrument over the sponge-tent, sea-tangle, or those other complex instruments is, that they do not carry with them septic poison. Although, as I have stated, Hegar's set is made of twenty-six pieces, I believe you may with advantage have a higher number; and the set I have the honour of exhibiting to-night consists of thirty-six pieces.

The members were much interested and Professor Dill was thanked for his kindness in showing his various instruments.

The Honorary Secretary submitted the report of Council which was passed.

The Treasurer Dr. Esler brought forward his financial statement for the year which showed a satisfactory balance £106-3-1 in hand.

The hour being advanced the meeting was adjourned for the election of office bearers till the 1st

Tuesday in October.

Adjourned Annual Meeting was held in Royal Hospital on Tuesday 7th October.

Present, Professor Dill President in chair, Drs. J. C. Smyth, James Smith (Shankill Road), McFarland, Esler, Wadsworth, Lindsay, Barron, Dempsey, John Moore, McConnell, and Mackenzie, Secretary. Dr. McKee was also present.

Mr. Fagan and Dr. Whitaker were proposed as President for ensuing session. Mr. Fagan was elected by 9 to 2.

Drs. Moore and Wadsworth—Vice Presidents.

Dr. Lindsay (10), J. W. Browne (8), McFarland (9) Dempsey (8), J. C. Smyth (8), James Smith (7)—Council.

Dr. Sinclair was elected Pathological Secretary.

Dr. Barron was elected Librarian.

Dr. Esler was elected Treasurer. (by acclamation)

Dr. McKenzie was elected Secretary. (" ")

Dinner to be on 25th November. Dinner Committee, President, Dr. Esler, Whitla, Professor Dill and Honorary Secretary.

R. F. Dill, President
11th November 1884

ULSTER MEDICAL SOCIETY

SESSION 1884–85

The First Meeting of the U.M. Society was held upon the 11th November in the Royal Hospital.

Present, Professor Dill Ex-President in the chair, Mr. Fagan President-Elect, Drs. Dempsey, J. C. Smith, James Smith, Wadsworth, John Moore, A. P. B. Moore, O'Malley, Lindsay, Sinclair, Whitla, Byers, J. W. Browne, O'Connell, and Mackenzie, Honorary Secretary.

Professor Dill in a graceful manner thanked the members for their kindness to him during his year of office as President and expressed his pleasure at retiring in favour of one for whom he had respect and regard.

Dr. Esler in a neat and feeling speech proposed a vote of thanks to Professor Dill (the retiring President) referring to the cordial and hearty manner in which Dr. Dill entered into everything that was for the interest and welfare of the members.

Dr. Moore seconded and Professor Dill responded to the vote of thanks which had been received and passed by acclamation.

The President-Elect (Mr. Fagan) then proceeded to read his opening address.

Paper:¹ GENTLEMEN,—I feel deeply sensible, I can assure you, of the honour you have done me by electing me as your President for the present year—an honour that is enhanced by the unanimous and hearty manner in which it has been conferred. It will be my earnest wish and endeavour to prove myself worthy of such, by upholding, in every way I can, the dignity that attaches to the honourable post of presiding over such an influential and intelligent body of gentlemen as the members of the Ulster Medical Society. Guided by the bright example of my predecessors, and relying on your kind assistance and forbearance, I hope that when my time arrives to vacate this chair it can be said of me that I have discharged the functions of my office in a not less satisfactory manner than those who have preceded me.

The first difficulty that besets my path is the selection of a suitable topic on which to address you. This wondrous epoch of ours, teeming as it is with startling innovations, is not wanting in the production of societies—religious, scientific, political and social, to promote and protect their various interests. Every profession, every trade has its societies to represent the different shades of thought and interest in each. The profession of medicine is not behindhand as regards the number and importance of its representative bodies. At the annual meetings of our great parent society we are

treated to Presidential addresses, learned orations on some of the absorbing topics engaging professional interest at the time, while the Presidents of Sections and the readers of papers thresh out pretty completely the several subjects of most interest in their departments of medical science. Again, if we look over the country we find numerous smaller societies working on lines similar to their great prototype, and if, together with the work done by those, we consider the addresses annually delivered in our Universities, Colleges, and Hospitals, it is not to be wondered at that there remains scarcely one spot unexplored in the regions of medicine.

It is not my intention to ask you to accompany me into strange regions on speculative inquiries, or to travel over again the well-beaten path that is so familiar to us all as “the review of the progress of medicine and surgery for the past decade.” Neither is it my intention to dwell on, as critic or panegyrist, the great achievements of such men as Pasteur, Koch, Lister, Wells, or Billroth, the great champions of our profession who, by their labours, are daily gaining fresh laurels—one set in the field of preventive medicine, the other by their skill and daring penetrating the most sacred chambers of the organism, and each succeeding year astonishing the world by some novel and bold surgical enterprise; such victories are of frequent occurrence, and our journals duly chronicle those achievements under such headings as hysterectomy, oophorectomy, splenectomy, ovariectomy, nephrotomy, cholecystotomy, and gastrotomy, as well as other exploits in the field of abdominal surgery.

To no such stirring themes do I invite you to listen. Mine will be a less pretentious one, but not less important. It is familiar alike to the pure physician and the pure surgeon, but more especially so to those engaged in general practice. I am sure every thoughtful and observant practitioner who has been some time engaged in professional work, when he looks back over his past labours, must be forcibly reminded of some weak points in the continuity of his practice, such as a wrong diagnosis, an erroneous treatment based on it, a case gone wrong owing to a timid, careless, procrastinating way of dealing with it.

In casting about for a subject, it occurred to me that I might with advantage dwell for a little on some of these points, and by directing our attention more particularly to them we might be able to detect and strengthen those weak links in the chain of our professional labours. To the enthusiast surgeon such an every-day subject will appear dull and uninviting, lacking as it does the glamour of novelty or daring enterprise, but to the thoughtful practical mind it will meet with the reception that its importance and usefulness deserve. As I grow in years and experience the more strongly do I become impressed with this idea, that we allow ourselves to be carried away too much by

¹ [Dublin Journal of Medical Science, 1885, v79, p344.]

speculative theories and novel practices, very often to the neglect of the first simple principles—a true appreciation of which, together with their timely and judicious application, are of infinitely more benefit to the race than the aggregate of the most brilliant discoveries recently made.

The subject-matter of my discourse, to which I will now direct your attention, is—the great importance of, 1st, accurate and early detection of disease and injury; 2nd, the adoption of a timely, judicious, and decided mode of treatment. A higher and more important function still than early detection is the prevention of disease and injury; and it can never be said of our noble profession that, whilst it might appear to be their interest to be indifferent to such, they have not repeatedly and loudly raised their voices, proclaiming with no uncertain sound the importance and necessity there is for observing the common laws of hygiene. In proof of this we have only to look to the labours and teachings and warnings of such men as Jenner, Pasteur, Koch, and Lister, the great apostles of “preventive medicine,” who have preached, and are still preaching, the gospel of sanitation, whereby not only individuals and communities but whole races have been and may still be benefited. Notwithstanding this, ignorance and apathy still prevail, and as the outcome of such, together with the inevitable tendency to degeneration inherent in our nature, the services of the physician and surgeon are still, and, I believe, always will be, in active requisition. If, then, we cannot hope to prevent the occurrence of disease and injury, it behoves us to try and recognise it in its earliest manifestations, for by so doing it can more effectually be arrested or brought to a satisfactory issue.

The first proposition, then, must forcibly commend itself to us, inasmuch as the more accurately the truth is known concerning any subject, the more efficiently can it be dealt with. On the medical attendant devolves the onus of finding out the truth concerning the cases brought under his observation, and on the acuteness of his diagnostic powers often hangs the well-being—nay, even the life of his patient. Ability as a diagnostician is one of the highest attributes of the physician or surgeon, for excellence in it demands that they be possessed not alone of many highly-developed physical qualities, and a large and varied experience, but presupposes as well an accurate knowledge of a wide range of scientific subjects. With all these qualities the highly accomplished consultant makes his mistakes in diagnosis as well as the humblest practitioner, and “Humanum est errare” may, with peculiar appropriateness, serve as a motto for all of us. I have somewhere heard the statement, and often seen it verified, that there is nothing more humiliating to the pride of our profession than the records of the post mortem room.

While there must always be differences in men’s diagnostic powers, there is one important particular in

which all should be equal, and that is the desire to leave nothing undone to enable us to make our diagnosis as accurate as possible. I do not propose to consider what should be the qualities of a good diagnostician, or the best methods to be employed in making a diagnosis, but I will draw your attention to what I consider to be some of the main defects to which not a few are liable:—

1st. A tendency to form a rapid conclusion on very slender data.

2nd. Putting leading questions to a patient.

3rd. Imperfect or ill-conducted physical examination, or no physical examination at all.

The first of these, we will admit, is a common cause of cases of mistaken diagnosis, and I think it can be accounted for in this way. Medical men in large practice would find it physically impossible to get through the amount of work they perform had they to carefully consider in detail each case presenting itself; besides that, they acquire through their large and varied experience a power akin to instinct that, from what I may call the physiognomy of disease, enables them to form, as a general rule, a very accurate diagnosis. That they are sometimes wrong, and evil results follow to doctor and patient, cannot be denied, and there are few of us that do not know or have not heard of cases, painful illustrations of this fact. I, some time ago, heard the following:—A man, who had been some days before in a drunken brawl, consulted his medical attendant for a slight headache and general contusions. A warm bath and some alterative medicine were prescribed, and he was told he would be all right in a few days. After a few days’ time the man, not feeling better, again consulted his doctor, who found his patient’s headache much worse, and also that he had vomited a couple of times. Still looking to the stomach as the cause of his disorder, suitable drugs were again prescribed. A few days after this the headache and vomiting ceased, but the patient began to lapse into a dull state, varied by occasional fits of restlessness and excitement. At this stage another practitioner was asked to see the case, who, after getting an accurate history, made a careful physical examination and found a small contused wound on the man’s head that up to that time had not been detected. The opinion then formed was that the symptoms were due to cerebral mischief, and treatment was accordingly directed to it, but notwithstanding this the man died comatose in a few days. Instead of rushing to the conclusion that the man’s headache depended on disordered stomach following his debauch, had his medical man carefully gone into the history of the case, followed up by a close physical examination, the probabilities are that an accurate diagnosis would have been made, a rational mode of treatment adopted, and, as a result of such, a life perhaps saved.

The second defect to which I wish to draw your attention is, “the habit of putting leading questions to a patient.” This practice very often results in a wrong

opinion being formed, for if the objective symptoms be not sufficiently well marked, the patient is questioned and cross-questioned, not so much with the view to elicit facts as to get confirmatory evidence of some hypothetical diagnosis already formed. Having once formed and expressed an opinion, it is astonishing with what tenacity we hold on to it, and any fresh symptoms arising, and existing ones becoming more marked, are bent and twisted to harmonise with our prejudiced view. Let a fresh mind be brought to bear on the case at this advanced stage; it will at once, by the light of the new and better-marked symptoms, arrive at a true diagnosis; and it will then strike us how strange it was we did not see the case in that light before.

The third defect—and a very grave one in making a diagnosis—is where no physical examination, or a very indifferent one, is made. I need not dwell on the disastrous train of symptoms that often follow in cases where physical examination has been neglected. Some of you have heard, no doubt, of patients treated for colic and dyspepsia, who, on being subjected to careful physical examination, were found to be suffering from a strangulated hernia. I have known cases of incontinence of urine where strychnine and other drugs were assiduously administered, with a view to render the bladder capable of retaining its contents when that viscus was distended to the point of rupture from inability to get rid of, except in drops, the accumulated urine. That such grave mistakes are occasionally made is unfortunately too true; and in well-marked cases, such as those mentioned, where the symptoms point strongly to the more than probable cause, and indicate the necessity for a physical examination, the neglect to do so must be attributed to the culpable carelessness or gross ignorance of the medical attendant. While a perfunctory examination is not so bad as no examination at all, it cannot be too strongly condemned, for while there is an attempt to comply with the form of examination, apart from the mere formality, it serves no useful purpose. It is not an uncommon thing, when a child suffering from a slight pain in a joint or limb is brought for professional advice, for the doctor to feel the parts as it stands beside him, and not detecting anything strikingly wrong, while he prescribes some simple application, gives the consoling opinion that it is nothing worth considering, and will come all right in a little time. The parent, now relieved of all anxiety, accounts for the symptoms as due to the child's nervous disposition, or to what is popularly known as "growing pains." But a condition of well-marked arthritis or osteitis soon after manifesting itself, rouses again the parent's anxiety, and the doctor is a second time consulted. The more decided symptoms now present demand a strict physical examination, followed no doubt by the conscientiousness that had such been done on the first occasion, much mischief might have been averted. I have met with cases where sedatives were assiduously applied

along the course of painful nerves of arm and leg, and hopes held out that with time, change of season or of climate, the pain would disappear, where a careful physical examination afterwards revealed a cancerous nodule in the axilla, or a similar malignant mass in the pelvis, as the true cause of the symptoms present.

There are two affections, of which I see a considerable number occurring with great frequency, and in which an accurate and early diagnosis is of paramount importance—I allude to cases of hip and spinal disease. In their early stages it is often a most difficult matter to make a correct diagnosis; the symptoms in each are obscure and ill-defined, and in the case of hip disease, singly, or even in groups, are not conclusively pathognomonic of this affection. Hence we may have pain in the knee, flattening of the buttock, flexion of the thigh, pain in the groin, stiffness of the joint, each and all of which are usually found in hip disease, and yet their presence is not conclusive of it, as these symptoms may be due to other pathological states. It is for want of making a thorough and complete physical examination that medical men, seeing one or a group of symptoms usually associated with hip disease, jump to the conclusion that it must be present, when they ought to remember that the same symptoms may be equally conclusive of a totally different condition. I knew a very eminent surgeon who, forming his diagnosis on the presence of one or two prominent symptoms, pronounced the case he was called to see to be one of hip disease; accordingly, he gave instructions to have the best room in the house given up to the patient, as her case would be tedious, and likely to confine her to bed for three, six, or perhaps twelve months.

His orders were carried out, but the cure was more rapid than he had anticipated; in a week after he saw her, the child one night passed a large quantity of pus per anum, and in three weeks was up and about. It was a pelvic abscess, not a case of hip disease; the more prominent symptoms present were common to both affections, and his neglect of making a careful and thorough differential diagnosis led him into the mistake he made.

The following case, that occurred in my own practice a few years ago, I think worth recording:—After I had concluded my lectures on hip disease at the Children's Hospital, the students of my class, during my absence, examined a case that was brought for me to see, and pronounced it to be one of hip disease. They detailed as present most of the symptoms common to the affection—viz., lameness, flexion of thigh, flattening of buttock, pain and swelling in the groin. And seeing the child, who was now dressed, walking with the characteristic gait, I coincided with the opinion expressed by them that the case was one of hip disease in its first stage. I told the mother of the child what my opinion was, and that a splint, which I then ordered, would be necessary. A few days afterwards, while the child was

waiting in bed for her splint, I happened to examine her, and finding some important symptoms absent, and others not well marked, my suspicions began to be aroused concerning the correctness of the diagnosis. I got the child out of bed, and noticing that she walked with more freedom than when I first saw her, I asked her if she suffered pain in walking, and, if so, where? She replied she had very little pain now, as her heel was nearly well. On examining the heel I found a little ulcer over the tendo-Achillis; this had existed for two or three months, being very sore at the time of her admission to hospital, and now much improved by the rest obtained. The presence and history of this little ulcer were quite sufficient to account for all the symptoms. To prevent straining of the sore she walked on her toes, with leg and thigh slightly flexed. Owing to the flexed condition of the thigh, the fibres of the gluteus became relaxed, and there was partial obliteration of the fold of the nates, with some flattening of the buttock. The pain and swelling in the groin were due to an enlarged tender gland—produced, no doubt, by the irritation of the lymphatics at the seat of the ulcer. I need scarcely tell you that the order for the splint was immediately countermanded, and the mother duly informed that the rest and other treatment had improved her child so much that a splint would not be required. It was a gratifying communication to her, and she expressed her hearty thanks for saving her child from a cripple's fate. This simple case illustrates very forcibly the liability there is to be led astray by what, *primâ facie*, is strong presumptive evidence of a certain well-defined disease; and the lesson to be drawn from it is that in all cases of the kind the patient should be subjected to a thoroughly searching and complete physical examination before hazarding a diagnosis.

In the first stage of spinal caries the symptoms are also very obscure; pain of an ill-defined character, and referred to regions remote from the spine, is the first warning given of commencing mischief; and I may here mention that at this early stage of spinal disease the case is generally treated by the physician, as the symptoms present point to diseased conditions that come more within his province than that of the surgeon. It is not an uncommon thing to find that cases have been treated for a long period for gastric derangement, and that it was only when actual deformity of the spine was manifest that the true nature of the ailment was discovered. In the same way cases of bronchial and laryngeal irritation have been drugged and sprayed, while the real offender, secretly doing its deadly work in the spinal column, was allowed to go on unnoticed.

A case came under my observation a few years ago of a young man who had been resident in England, and was sent home by his medical adviser, after four months' treatment for a kidney affection, in the hope that his native air would restore him. A careful examination of his case revealed a spinal caries in the dorso-

lumbar region. I was able very clearly to trace the disease to an injury sustained three months before he began to complain. For treatment I recommended rest in the recumbent position. After a little the pains in the loins disappeared; later on jackets, at first of plaster-of-Paris, then of felt, were applied; and I was informed that in some time over a year he was about quite well. For a series of cases illustrating this aspect of the subject I would refer you to Mr. Hilton's classical "Lectures on the Diagnostic Value of Pain."

I have now, in a very desultory and superficial way, brought under your notice some points indicating the necessity for an accurate and early diagnosis in all cases of disease and injury, and we have seen that this can be accomplished only by obtaining a true history of each case, and by a careful consideration of all symptoms, both objective and subjective, after making a thoroughly complete physical examination. We have seen how wide of the truth single symptoms and even groups of such are sometimes apt to lead us; how a flexed thigh, flattened buttock, and a painful swelling in the groin, may exist from other causes than hip disease; how pain in the knee is not conclusive of knee mischief, or even of hip mischief, with which it is mostly associated, but may be due to rectal, sacro-iliac, or other pelvic mischief; how the first warnings of spinal disease manifest themselves, as pains in the regions of the chest, stomach, kidneys, or bladder; and considering all these facts, must we not be forced to the conclusion that it is only by the most careful, thorough, and patient examination and study of each symptom and group of symptoms that we are likely to arrive at an accurate diagnosis.

I will now ask your attention for a moment to what follows as a rational sequence of our first proposition—viz.: "The adoption of a timely, judicious, and decided mode of treatment."

The early and accurate detection of disease and injury is of the first importance, for by the light thus obtained appropriate treatment can be more effectually applied. Up to this point direct benefit to the patient has not been considered, and although we sometimes meet with patients who take an interest in the niceties of diagnosis, and the study of pathological states, the majority come for treatment, which they want carried out quickly and successfully.

By "timely treatment" I mean that which is adopted as soon as the case is brought under the notice of the medical attendant. We know that, owing to the ignorance or carelessness of the patient or friends, cases are not always seen at their commencement—indeed, many not till considerable mischief of a preventable character is done. That, however, is not the fault of the medical man, whose responsibility begins only at the moment he sees his patient for the first time. When a diagnosis is made, treatment judicious and decided should at once be put in practice.

The habit of procrastinating when treatment is required, is a thing that cannot be too strongly censured, especially in cases of great urgency; the number of lives lost, and the amount of suffering entailed, by postponing treatment for even short periods, if it were possible to calculate such, would be appalling to contemplate. In apparently trivial cases, where symptoms are ill-defined, while not playing the part of alarmists, it is wise to give due caution against doing anything that might be injurious, or likely to develop mischief, until every suspicious sign of it had disappeared. One medical man, disdainful of such slight warnings, assures his patients that they need not mind, that they will be all right again after a little. Another practitioner, of a more prudent disposition, advises them to observe caution, avoiding this or doing that, till all suspicious symptoms disappear, and should there be at any time the slightest retrograde tendency, to have their case again inquired into. I think you will agree with me that although in many cases the sanguine expectations of the one are verified, still, on the whole, there is less cause for regret by hearkening to the prudent warnings of the latter, who, anticipating mischief, subjects his patients to a timely and judicious treatment, and, next to the prevention of the disease or injury, does the best thing that can be done for them. In better-marked cases still, we sometimes see this tendency to make light of them, and not infrequently do we hear patients say: "I consulted Dr. A. or Dr. B., but he did not think it would signify, so I paid no further heed to it." And do we not, unfortunately, but too often see painful cases of bone disease, spinal and joint disease, as well as various other affections, both medical and surgical, the outcome of this reprehensible practice of making light of, or ignoring, these primary, though faint, warnings of brewing mischief.

To conduct successfully, through the anxious and tedious stages of disease and convalescence, cases of morbus coxæ or spinal caries, is creditable alike to the patience, judgment, and skill of the surgeon—to save by an amputation a life endangered by a disorganised limb, or to preserve one of the members by a successful excision, are triumphs in which he may take a pardonable pride, but a greater triumph still, and one worthy of a higher meed of praise, is to make an early and accurate diagnosis of disease, and to crush it out in what I may term its embryonic condition.

Unfortunately this, the noblest and most useful quality of our calling, is the least recognised by those who most benefit by it—nay, more, I have known cases where the medical man was not alone not thanked, but strongly censured instead, for what were considered opinions too hastily expressed, and treatment unnecessarily imposed. Instances of this are, I am sure, familiar to all of us. A few years ago I saw, in consultation with a distinguished medical friend, a child who had well-marked symptoms of incipient hip mischief. She was

immediately subjected to a decided line of treatment, which was rigidly carried out for a month or six weeks; by this time the joint was so much improved that the friends, doubting the opinion expressed by us, took her to a metropolitan surgeon, who assured them that there was nothing wrong with the child, that all she required was attending to her general health. While we might indulge in the consoling reflection that we saved that child by timely and decided treatment from the possible fate of a cripple's life, I have reason to know that we incurred the parent's censure for the expression of alarmist views and unnecessary restraint put on the patient. Did time permit, I could quote numerous instances of a like character, but I will only relate this striking one, showing the value of the public opinion on matters purely professional, told by Sir James Paget of a distinguished London surgeon who, while operating on a gentleman for strangulated femoral hernia, with great carelessness cut right into the intestine. Fæces flowed out, and all the miseries of a wounded intestine followed. After much anxious care, at last the patient recovered. His firm conviction was that by this very incision into his bowel he had escaped some dreadful calamity, and that nothing but the most extreme skill could have either made the incision into the bowel, or recovered him after it; and he presented the surgeon who had done this for him with a very handsome gold snuff-box.

For the very reason of this inability on the part of the public to judge rightly, it is all the more incumbent on us, rising above personal considerations, to stand in their place and help them. In obviously well-marked cases, urgently demanding treatment, there can be no excuse for procrastinating; pressure of work, or want of confidence in one's power to deal with the case, is no justification for delay; deferring treatment on such grounds, or in the vague hope that by some lucky chance it will come to a successful issue, is reprehensible in the highest degree. Such cases should not be left uncared for one moment longer than is absolutely unavoidable; and if from any cause the necessary attendance cannot be bestowed on them by the medical man first consulted, he should seek the assistance of another, whose time is less occupied, or who could bring special knowledge and experience to bear on them. Not infrequently do we meet with cases, painful examples of the results of this procrastinating or difficult disposition of the medical attendant.

A short time ago I attended a poor fellow who suffered from urinary fistulas and vesical catarrh; he was reduced to the lowest ebb by prolonged and intense suffering. Some months previously he got a fall on his perinæum, rupturing the urethra; this was followed by urinary extravasation. There were delay and indecision in dealing with the case, and it was only when the mischief was done that a second medical man saw it and adopted the proper treatment of making free incisions

over the infiltrated area. It was too late, however; the whole of the integument covering the lower half of the abdominal wall, as well as the scrotum, sloughed, and the enormous extent of raw surface, with penis and testicles exposed, was, I heard, fearful to witness. I performed a cystotomy for the relief of the intensely painful bladder symptoms, which placed him in comparative ease for some months, and then he died. I give this as an example of the appalling and fatal results that may follow the neglect of a timely, judicious, and decided mode of treatment. Cases of ruptured urethra are common in hospital practice, and when seen soon after the accident, while the swelling and infiltration are confined to the perinæum, are easily and successfully dealt with. The practice I follow is to pass a sound down the urethra as far as the seat of mischief, and make a free deep incision on it, and multiple incisions about the part if its state demands such. I have never seen any of these cases go wrong when dealt with early and in a decided manner, and rarely have I seen constitutional disturbance or suffering of any consequence in connexion with them.

Another form of affection that terminates badly, if not dealt with in a similar way is periostitis. If seen in the very early stage, rest, elevation of the limb, perhaps cold applications, and general antiphlogistic treatment may arrest its further progress; but if not seen till a later stage, when there is great pain, swelling and tension of the part, and it be not dealt with vigorously, the danger to life and limb are very great. I have seen prolonged suffering followed by extensive necrosis, blood-poisoning by which some lives were lost, and others placed in great jeopardy, and all for the want of a timely and proper incision.

Let me explain here what I mean by proper incision. Some men persuade themselves that when they make a puncture and draw blood they have complied with the requirements of the case. If their object is to draw blood and they get sufficient, well and good; but in cases such as periostitis, there can be no more mischievous practice. Owing to the swollen, congested state of the tissues, an incision that appears deep and bleeds freely is frequently useless, for its object is not attained, the periosteum is not reached, and what was meant for good is sometimes only the means of creating further mischief. The motive for interfering is to relieve periosteal tension, which if not accomplished will end in the death of the bone. Hence, to do this effectually it is necessary to pass the knife well down to the bone, and keep the blade in close contact while making the requisite free incision. In this way the tension of all the parts is relieved, and the treatment, so far, is judicious and thorough. The same may be said of cases of diffuse inflammation, when spreading under fascial or aponeurotic structures, so often seen in the extremities following injuries and operations, and it is unfortunately no uncommon thing to see poor creatures who

have survived a protracted period of painful suffering, carry about with them a seamed, scarred neck, a clawed hand, or a crippled, useless limb—monuments of procrastinating habits or timid peddling surgery. Let me not be understood to convey that all such cases are the outcome of indifference or incompetency on the part of the medical attendant. Nothing is further from my mind. They may occur in the hands of the most competent surgeons, for the result may be due in one case to the fact that it was not seen till the mischief was done; in another to the dogged, ignorant obstinacy or fear of the patient to submit to the proper treatment; in others, again, to some defect in the organism, which prevented it responding to treatment, though most judiciously and efficiently applied. The two grand principles of “rest” and “relief of tension,” on which depend the successful treatment of many diseased conditions, especially in surgical practice, cannot be too strongly enforced. It behoves medical men, then, while recognising their value, to see that they are carried out in a thoroughly efficient manner, so as to accomplish the object at which they aim, otherwise they are not alone powerless, but faith in their efficacy being shaken, much mischief may occur for want of their proper application.

Travelling with a professional friend a few weeks ago, I saw him intently and with evident satisfaction observing the back of his hand, on which were visible four linear scars extending the whole length of each metacarpal bone; he next vigorously put his fingers and hand through their various movements, and, finally, seizing mine, he squeezed it with a force that, if it indicated the strength of his regard for me, left no doubt of my being very high in his estimation. He said, “It’s all right again; I can do every thing with it; it is quite as strong and useful as ever.” He was treated by me some time previously for a very bad form of inflammation of the hand, following an injury; it had been poulticed and punctured before he came up from the country to place himself under my care. The scars referred to were the result of the free incisions practised, and after which, with absolute rest and other appropriate treatment, he made an uninterrupted recovery.

This simple case forcibly illustrates the value of the efficient application of the principles already mentioned, and I am sure most of those about me now can record not one but many cases equally successful by the application of timely, judicious, and decided treatment.

In the great and important subject of joint disease and injury, the value of the application of these principles cannot be too strongly impressed on the minds of medical men, and we frequently see that, owing to want of attention to them, injuries, at first trivial, slowly but surely acquire a condition that very often ends in confirmed disease, deformity, or death. While I am prepared to admit that perverseness, gross ignorance, and prejudice on the part of patient or friends, often thwart

the medical attendant in his endeavours to deal efficiently with the early stages of disease in joints, still I am forced to the conclusion that a great deal of mischief of a preventable kind is allowed to take place, owing to the fact that some medical men make light of, or do not appreciate the importance of, early and decided treatment in the first manifestations of disease in these structures.

And now, gentlemen, although many subjects present themselves to my mind in connexion with which the consideration of the propositions first made would be both interesting and instructive, I find that time will not permit it—indeed I feel bound to apologise for the length of time I have already detained you with what will appear to many, I am sure, very commonplace matters, and I hope you will not consider that I have addressed my remarks to you as one who felt he was enunciating views that were not already as familiar to you as to himself. Believe me, I have too keen a perception of my own shortcomings, and too true an estimate of the high professional excellence of my brother practitioners in Belfast, to address them in any such spirit; but you will admit that, owing to the anxiety and hurry entailed by increasing professional labour, we are all of us apt to overlook the little things both of principles and practice that are of the first importance in the every-day work of our profession, and that we can all benefit by repeated and sharp reminders of our backslidings in these matters.

While we are considering some of the important duties we have to perform towards our patients and the public, we are not to forget there are other duties no less strictly demanded of us towards ourselves, our professional brethren, and the honourable calling to which we all belong. The elevation or degradation of the body depends on the aggregate of the acts of its individual members, and in proportion as they are honourable, useful, and enlightened, will it rise in general estimation. Hence, it is incumbent on each of us, by the faithful and conscientious discharge of his duties, by his high moral tone and dignified conduct, to aid in elevating it in its social status, and increase its power for well-doing; and, while acting thus his own part, he is not to be indifferent to his brother who, through carelessness, oversight, mayhap ignorance, fails in his duty to his patients or his profession, but should from mutual interest, as well as in common brotherly charity, hasten to shield him from the hard censure of an unsympathetic public.

Gentlemen, I do not know any means that is more likely to promote such objects more effectually than the Society I have the honour of presiding over this Session. Through it the scientific and social aims of our profession are promoted, interchange of views on the ever-varying questions of the day takes place to our mutual advantage, biased opinions are altered or modified, a spirit of inquiry is fostered, our knowledge and mode of

treating disease are brought more in line with the advanced practice of our time, and our local band is kept well in the forefront of the ranks of our profession.

The promotion of the more intimate social intercourse of its members is not the least important function of this Society. It has not been so fortunate in accomplishing this as one would wish; still we must endeavour, with the facilities at our disposal, to do what we can to encourage it; and I anxiously look forward to the day when a university or college club, in which the medical element will form no insignificant part, will be established amongst us to further still more this desirable object. I believe such an institution will promote the social elevation of our body, smooth any little professional acerbities, and exercise a healthy, restraining influence on erring members by bringing the weight of our united opinion to bear on them.

We have lately seen what the profession in Belfast and the North of Ireland can do when it wishes to put forth its strength. The noble reception it gave to the British Medical Association was the theme of praise and admiration of our numerous visitors, and redounded to the honour not alone of our local profession, but to that of the whole community. We cannot then plead incapacity. As a professional body we are strong enough, and capable of developing our present Society, or forming and fostering a medical club worthy of our body and the important community in which we live. Whether emanating from these modest rooms or more pretentious halls, let the spirit of our Society be ever active in promoting the interests of our body, both as regards our relations to one another as well as to the outside public; and let each member, acting in conformity with that spirit, play his part honourably and well. Let the senior members and those whom the propitious wave of circumstance, aided, perhaps, by ability and honest hard work, has landed into the pleasant places of our profession, sustain the dignity and prestige that are supposed to be attached to the position they occupy. Let remuneration for their services be commensurate with their position and the costly requisites and luxuries of their clients. Let them remember that accompanying such honourable and lucrative positions is also a responsibility towards their less favoured brethren. They should be the standards by which younger members would gauge their professional relationship with the public; and as it is with the learned profession of the law, when a counsel gets silk it debars him from a certain class of practice that becomes the right of the junior brethren, so it should be with us. Those fortunate members who have attained commanding positions should refrain from injuring the prospects of their junior brethren. Should they act in this manner, all interests will be served; the province of the general practitioner will not be encroached on; the labour of the consultant is lessened, while his remuneration is increased; and the patient, often valuing the

services in proportion to the expense and difficulty in securing them, feels satisfied.

As regards the general relationship that should exist between all of us hard workers, whether specialists or general practitioners, let us try and be animated by a spirit of brotherly love and charity; let us bear and forbear with one another; let us, by kindly advice and practical assistance in times of need, lighten the burden that is imposed on us all, pressing with greater force on one than another; let us, by honourable, straightforward dealings in our complicated relationship to our patients and to one another, advance our own and our patients' interests and the honour and interests of our profession. Acting in this manner, our power and efficiency will be strengthened to enable us to carry on with unwearied vigour the great crusade against disease and injury that seem to be the inevitable inheritance of our common humanity.

Dr. J. W. Browne proposed and Dr. Dempsey seconded and Professor Dill supported a vote of thanks to the President for his valuable and practical address.

Dr. Esler proposed and the Secretary seconded that the following gentlemen should be balloted for: Dr. R. Purdon, Dr. Bigger, and Dr. Poole.

John Fagan, President
9th December 1884

Session 1884–85. The Second Meeting of the Society was held in the Royal Hospital upon Tuesday evening 9th of December at 8 o'clock.

Present, Mr. Fagan President in the chair, Drs. Dill, Browne, Dempsey, Whitla, St George, O'Neill, Sinclair, Esler, Kevin, Moore, O'Connell, and Mackenzie, Honorary Secretary.

The President having drawn attention to the death of Dr. Wadsworth, one of the Vice Presidents of the Society, Professor Dill moved and Dr. Browne seconded that the Honorary Secretary be instructed to write a letter of condolence to the relatives of the late Dr. Wadsworth.

A ballot was taken for the following gentlemen who were elected unanimously members of the Society: Drs. R. D. Purdon, Poole, and Bigger.

Dr. Whitla proposed, Dr. St George seconded, and Professor Dill supported a resolution that Dr. Esler be elected Vice President in the place of the late Dr. Wadsworth.

Dr. St. George read a paper on genu valgum illustrated by a case successfully treated by means of "splints" without osteotomy.

The President showed two patients, and Dr. Browne showed two patients, upon whom the operation by McEwan's method had been performed with the most satisfactory results.

An interesting discussion in which almost all the members took part ensued on the various methods of

treatment and modes of operation recommended for the cure of genu valgum.

Dr. Whitla exhibited vertebræ from the Irish Elk showing a rheumatic arthritis as illustrated by specimens of human bones.

He also exhibited a patient suffering from pseudo hypertrophic paralysis.

Dr. Whitla proposed Dr. Ward of Lisburn as a member.

A Council meeting to be summoned soon as possible to discuss place of meeting and any new arrangements which might add to the interests of the meetings. Also the procuring of a new minute book.

Since last meeting a successful and enjoyable dinner of the members and visitors was held in the Royal Avenue Hotel. The members all expressed themselves as being highly pleased with the manner in which the dinner was served.

The following members and guests sat down: the President Mr. Fagan in Chair, Professor Dill Ex-President Vice-Chair, Surgeon Major Thomson A.M.D., Drs. Dunlop, McFarland, Armstrong A.M.D., Browne J. W., Wheeler Senior, St. George, O'Neill, Patrick, Graham, Bigger, Sproule, McConnell, Esler, John Moore, Kidd, Cuming, Harkin, Whitla, Dempsey, O'Connell, J. C. Smyth, James Smith, Gilmore, Poole, Purdon, Lindsay, Barron, and Mackenzie Honorary Secretary. 18/6 and 10/6

John Fagan President 23rd December 1884

1884–85 Third and Special Meeting of the Society was held in the Royal Hospital upon Tuesday 23rd December at 8 p.m.

Present, Mr. Fagan President in the chair, Professor Dill, Drs. Kevin, A. P. B. Moore, John Moore, Whitla, R. D. Purdon, Gilmore, and Mackenzie, Secretary.

The minutes of last meeting were read and confirmed.

The Secretary read a letter from Mrs Wadsworth in reply to the letter of sympathy sent from the Society on the death of Dr. Charles Wadsworth.

The Secretary read the following report from the Council:

"Your council being desirous of increasing the interest of the members in the meeting of the Society and feeling that your place of meeting is very far from being comfortable or attractive, with a view of bringing the members into closer fellowship one with another, recommend (1) That the place of meeting be changed for this session from the Royal Hospital to the Belfast Museum; (2) That the evening of meeting be Thursday instead of Tuesday (on account of the Museum being occupied on Tuesdays) (3) That tea should be served to the members at 7:30 o'clock.

Some of the junior members of the society felt that the meetings were very lukewarm and that there is a want of sympathy displayed one with the other

and in order to bring about a closer acquaintanceship, and cause a firmer bond of union to exist among the members of the Society, your council recommend the 'Social cup of tea'.

Your council express the hope that the members will throw more zeal and energy into the working of the Society by attending the meetings in greater numbers and assisting the secretary in procuring pabulum."

Dr. John Moore proposed and Dr. Esler seconded that the change of meeting place mentioned on the circular and recommended by the Council take place for this session. Passed unanimously.

Professor Dill proposed and Dr. Kevin seconded that the change of evening of meeting mentioned on the circular and recommended by the council from Tuesday till Thursday be adopted. Passed unanimously.

Professor Dill proposed and Dr. R. D. Purdon seconded that tea should be served at 7:30 and business begin at 8, and that the expense should be borne by the funds of the Society. Passed unanimously.

Dr. John Moore proposed and Dr. Kevin seconded that the rules of order of procedure at meetings be adopted and printed with next circular. Passed unanimously.

The Secretary read an interesting proposal from Mr. N. H. Patterson Honorary Secretary of Belfast Natural History and Philosophical Society that the Ulster Medical Society should have the use of the two rooms at the left of entrance hall in the Belfast Museum on alternate Thursdays for 10/- per night (including gas-fire and use of tea equipment). No attendance further than the opening of the door.

Thursday, January 8, 1885.

The PRESIDENT in the chair.

The President, Mr. John Fagan, F.R.C.S.I., made the following remarks at the meeting on 8 January, 1885.¹

On the very threshold of the New Year let me express the wish that it may be a happy, useful, and prosperous one for all of you; and that it may see our Society extending its usefulness, benefiting not alone its own members, but the whole profession within the sphere of its influence, and through them promoting the well-being, health, and happiness of the community in which we live. The year 1885 is a somewhat eventful one for this Society. After a lapse of twenty-three years it has, I hope, in its wisdom thought well of changing its abode. During that lengthened period it has carried on its work within the walls of the Royal Hospital—a congenial place, we must admit, for prosecuting its operations. But the council of your Society has for various reasons recommended the change, and this has been confirmed at a special meeting of the members. I sin-

cerely trust that the change will be a beneficial one, and that the Society under its somewhat altered conditions will carry on its work with renewed and increasing energy.

It is a somewhat strange coincidence that the last meeting of the Society in the place it occupied since its formation should be the last meeting for the year, and that the last minute signed should also terminate the book that holds the records of this Society since its inception. We are not alone turning over a new leaf; we are getting into a new book and a new domicile with the New Year. Let us hope that this marked change will be for the benefit of the Society, and that when the last page of this new book is filled in it will present a record of honest useful work that will redound to the credit of the labourers who took part in it.

It may interest some of you to hear the names of those who attended the first meeting of the "Ulster Medical Society," which was held in the General Hospital on the 4th May, 1862. There were present on that occasion—Professors Ferguson, Gordon, Reid; Drs. Browne, Murney, Mulholland, Corry, Johnston, Magee, Stewart, Patterston, Pirrie J. W. T. Smith, William MacCormac, David Moore, Dill, Brice, Smyth, Bryce, M'Gee Murray, Scott, Halliday, and Whitaker. And of the names I have mentioned the only one appearing at the last meeting of the Society, held in the Royal Hospital on December 23, 1884, is that of our respected and energetic ex-president, Professor Dill. To advocate the advantages to be derived from a Society such as this before such an audience would be a work of supererogation. Its usefulness is patent to all; but, while we admit its usefulness, I am sorry to say that the profession in Belfast does not enter as heartily and thoroughly into the practical work of the Society as the reputation of its members and the size and importance of the community would demand. If we look to the metropolis and provincial towns of the sister country, we find their Medical Societies—not one, but many—in an active and flourishing state, at which the leaders of the profession, both young and old, many at great personal inconvenience, are constant attendants. And if we notice the reports of those Societies in our weekly journals, we constantly meet with the names of such men as Sir James Paget, Sir W. Jenner, Sir Andrew Clark, Sir Jos. Lister, Sir W. Gull, Sir W. MacCormac, Mr. Bryant, Mr. Hutchinson, and other leaders of the profession, as presidents, readers of papers, or members taking part in the discussion. The benefit of the presence and the expression of the matured views of such experienced members cannot be too highly estimated. I entertain the hope that the meetings of this Society will be honoured as well as benefited by a larger representation of its senior members than it has been heretofore. The amount of clinical material available in Belfast is enormous, and this, it is to be hoped, will be turned to useful purposes.

¹ [Dublin Journal of Medical Science, 1885, v79, p156.]

We have, representing the various branches of the profession in this town, men of high culture and vast and varied experience, whose opinions in discussions on the subjects with which they have specially identified themselves would form valuable contributions to medical science. I can well imagine the benefits that would accrue to this Society and to the public by a discussion on such subjects as the present outbreaks of scarlatina and typhus fever, to the latter of which one of our active young members has lately fallen a victim. The diseases of the viscera offer another fruitful field in which we may labour with advantage. Physicians have brought the subject of diagnosis to such a high state of perfection that diseases of the hidden organs, hitherto obscure and ill-defined, can now be demonstrated with astonishing accuracy. Owing to the vast strides that are being daily made in this department of medicine and surgery, and the startling innovations in practice following one another in rapid succession, there will be no lack of interesting and useful subjects for discussion. Through the combined efforts of physicians and surgeons some very creditable work in connexion with abdominal and chest surgery has appeared in the "Transactions" of this Society, and if, up to this, no novel instance in brain surgery—a subject so prominently before the profession at the present time—has been brought under your notice, I hope in a very short time to bring before you a case in which I trephined the skull for a brain affection in a child three years old. The patient has progressed favourably since the operation, now nearly three weeks past; and while not too sanguine as to the child's ultimate recovery, I have every reason to hope that I shall be able to show her to you when I am giving particulars of her case.

With a rich vein of material at its command, and with, as I hope, the active co-operation of all its members, both young and old, I see no reason, gentlemen, why the Ulster Medical Society should not hold a prominent place among similar institutions throughout the kingdom.

COMPILER'S NOTE

As will be seen from the extract above, the meeting of 23rd December 1884 was the last of the year and the last to be held in the Belfast Royal Hospital before moving to the Belfast Museum; the minutes of that meeting were the last to be recorded in the first minute book belonging to the Ulster Medical Society.

It is here that this collection of the records of the Ulster Medical Society and its predecessors will also end. It is to be hoped that the records of the Ulster Medical Society from 1885 onwards will, one day, be similarly collected.

Appendix

The Nature of the Fevers of Belfast in the early 19th Century¹

by
John Stephens Logan

Almost any account of fever in Ireland must begin with famine. It seldom needed any extraordinary event to bring about famine in Ireland. The small tenant farmer, the subsistence farmer, like his fellows throughout the world had, and has, no certain harvest. It is still true as the poet says that:

He toils and he dare not stop;
His life is a long drawn question
Between a crop and a crop.²

Uncertain weather and plant diseases sufficed to cause famine five times in the 18th century, that is in the 1700s. And, as usual, fever followed famine; that is fever became epidemic, above and beyond its usual endemicity; because of the destitution and social disruption, and the wandering of people that follow famine. But the scarcity and dearth of 1816, 1817 and 1819 were exceptional. An extraordinary event had happened.

In 1815 the volcano of Mount Tambora in the island of Sumbawa in the East Indies erupted. It killed tens of thousands locally by explosion and falls of ash. It was to kill tens upon tens of thousands far across the world by its remote consequences. It is calculated that 150 cubic kilometres of volcanic dust entered the upper atmosphere. This dust spread around the world in the upper atmosphere and lingered there, perhaps for as long as two years. This high atmospheric dust, this dust veil, interrupted the sun's rays, made the weather cold, and spoiled the harvest of 1816, in North America as well as in Europe. 1816 was a year without a summer. The harvests failed, and 1816 and 1817 were famine years. Grain prices doubled in Europe and the United States.

Death rates rose over Europe. There were tens of thousands of deaths in Hungary from starvation. Similar deaths in Eastern Switzerland. In Vermont in New England farm families lived on hedgehogs and boiled nettles.

In Ireland the wheat, oats and potatoes failed. The poor harvest of 1816 was consumed by the end of the year. There can be no carry-over of potatoes and there cannot have been much carry-over of wheat or oats. The subsistence farmers had little, sometimes nothing, to eat, and no money to buy; and if they were bad, how much worse the landless labourers. Consequently in

early 1817 those worst affected abandoned their homes to try to live by begging, and as usual in famine, they made for the towns, including Belfast. In Munich beggars appeared from all directions, as if they had crawled out of the ground. (Let us be thankful nowadays for grain mountains and never complain that we have them. A reserve of grain is a great protection.) In Belfast, as in the rest of the island, fever became epidemic. Doctor S.S. Thomson, physician to the Frederick Street Hospital, now the Royal Victoria Hospital, gave this account of the rise of the epidemic:

I consider the predisposing cause of the present epidemic to have been the great and universal distress occasioned among the poorer classes by the scarcity which followed the bad harvest of 1816, together with the depressed state of trade and manufactures. The deficiency and bad quality of food. The want of cleanliness in the persons and dwelling of the poor. The contagion rapidly spread by the numbers wandering about in the search for subsistence."

McSkimin described the state of affairs in Carrickfergus.

1816. Both summer and autumn of this year were cold and wet: hence the crops were retarded in ripening, far beyond their usual season. On the 16th September the reaping of corn commenced here, but very little was cut before the middle of October, and on the 1st November many had not even begun their harvest. In December, much grain still remained in the fields, and some was even to be seen out in January. Markets of course advanced. On the 15th May, 1817, oatmeal sold at 5s.5d., and wheatmeal at 4s.2d. per peck (2 gallons); both were bad in quality. The ports being now open, a considerable quantity of rye flour was imported into Belfast from America, which was of much service. On the 11th June, oatmeal sold at 6s.4d. per peck, and all other provisions were high in proportion. The calamity occasioned by this dearth, was much heightened by many tradesmen and labourers being destitute of employment, and a typhus fever setting in early in the spring of 1817, reduced many of the working classes to a state of the greatest misery.

In September and October the fever increased to an alarming degree, and a meeting of the most respectable inhabitants of Carrickfergus was held, who entered into a subscription for the relief of the poor, and to establish a Fever hospital. It was opened on the 4th November 1817 and closed on the 3rd June 1818. The hospital was about a mile from the town in the

¹ [Part of an Address to the Belfast Division of the British Medical Association, 1988.]

² [Rudyard Kipling in: The Masque of Plenty, Departmental Ditties and Other Verses.]

Middle Division. The total number admitted was 114, 103 were dismissed cured. Six died. The greatest number of patients at any time was 26. £815.7.5½ had been expended on the hospital and relief of the poor.”

The mortality of 6% is not the mortality usual in untreated typhus or relapsing fever and would be consistent with that of trench fever.

Belfast has had three fever hospitals. The first one had 3 sites—the first site in Berry Street, 1797. The second on the corner of Smithfield and West Street and the third—purpose built—in Frederick Street. Next came the Union Infirmary Fever Hospital, “plain but not inelegant,” and 70 years later Purdysburn Fever Hospital. Belfast’s was the second fever hospital in Ireland. Limerick was first but it began in a shed. Berry Street was a house. In Frederick Street the new hospital was hurriedly completed, opened with the plaster still wet on the 1st August 1817, and was filled immediately. There were sometimes 200 patients and more in the 100 beds. There was no room for ordinary medical and surgical patients at that time, and little for years to come. In the three years 1817, 1818, 1819 it admitted 3527 patients. (Malcolm). How did they manage? There was the nursing staff, and there were three attending physicians, in some years only two; and no one else. No resident staff. No junior staff. There was an apothecary who dispensed 10,000 prescriptions a year and later was supposed to act as clinical clerk to the physicians and to assist at operations. One might wonder how it was done. The truth is I think that it was a nursing hospital. Physical examination was minimal. There were no special examinations. The physicians were really directors of nursing, and drug treatment in the best hands was very restrained, indeed minimal.

We should recall what they meant by fever. The clinical thermometer for practical use had not been invented. There were no temperature charts. The physicians of the time defined Fever much like this. The patient is affected by rigors, by languor, stupor, headache, giddiness, pains in the back and loins, anorexia, thirst, burning heat over the body, a quick pulse, and incapacity for exertion; and all this is not due to any local disease. It was agreed that the fever could not be arrested, it had to run its course. But the mortality could be diminished by nursing. And the risk to others could be lessened by isolation and destroying the contagion in the clothes. Measles, smallpox, scarlatina, tuberculosis or the fever of an abscess are not fever within their definition.

Clinical examination indeed must have been mostly confined to inspection. Percussion was not much practised till the 1820ies. Use of the stethoscope reached the hospital in 1828 (the year James McDonnell retired). One country doctor, when asked about splenic enlargement, said he could not tell, because he had no facilities

for post-mortems. He can never have palpated the abdomen. But they took the sick in, bathed them, gave them clean clothes, put them to bed, and boiled or hot ovened their own clothes “to destroy the contagion”. They seem to have known that that would kill lice but it never occurred to them that the fever, or fevers, were louse borne, though it had been suggested long before. And they observed the course, or courses, of the fever. That will be important later. In those first eleven years in Frederick Street, James McDonnell appears to have ruled the hospital and to have written the annual medical reports. I judge that from his position, from the style, and because when the committee directed that the medical report be signed in future, it was signed by McDonnell. He prided himself in the simplicity of treatment in the hospital. They did not use bleeding (that was contrary to the practice elsewhere) and they did not give mercury. Since 1797 he said, except two or three, no patient in typhus had been bled. Simple laxatives, acidulated drinks, occasional wine, ventilation and cleanliness. A reliance on the effects of nature. Of 370 male fever patients who recovered not one was bled, blistered or mercurialised after admission, and no emetics. Small doses of supertartrate of potash, infusion of roses, infusion of gentian, and wine were used.

McDonnell resisted to the end any attempt to distinguish different kinds of fever. Cases of fever, he said, differ only in degrees of violence, not in kind. Fever he maintained is synonymous with typhus, continued fever, low nervous fever or putrid fever. There was no new fever. Of course he was wrong. The mortality was not that of pure typhus. Moreover elsewhere, and even in Belfast, physicians were observing cases of fever which remitted and relapsed. Such early remissions and relapses could not be typhus. It has long been clear that McDonnell’s fever included not only typhus but relapsing fever. Now louse-borne relapsing fever due to infection with the spirochæte *Borrelia recurrentis* is a serious illness, often with hepatitis and jaundice, with a considerable mortality of its own. Too many patients recovered for all the fever to be louse-borne typhus or louse-borne *Borreliosis*. There is a third louse-borne fever (which also relapses) and it is my contention that many of the fever cases were really louse-borne trench fever due to infection with *Rochalimæa quintana*. Trench fever had been described for a century or more in eastern Europe under various names, but it came to the general knowledge of the profession in the Great War (1914–18). At that time huge epidemics swept both the British and German armies, louse infested as they both were. The disease was epidemic in the trenches of the Western Front, as well as being epidemic in the east on the Russian front. But by that time the louse-borne fevers had so much diminished in the U.K., that memories of what they had been, had faded. Arthur Hurst in 1942 asserted, quite unjustifiably, that trench fever had never occurred in England. He could not possibly know.

He might properly have said never identified, or, if identified, forgotten.

We may presume that among the fevers of those days brucellosis and Q fever were present but not distinguishable, and certainly numerically less important.

Light began to dawn in Belfast when McDonnell retired to the consulting staff in 1828. In the next annual report S. S. Thomson and W. M. Wilson describe relapsing fever. In 1835 Robert Little (recently Sir Peter Froggatt revived his memory) was writing with insight. He could not think that local inflammation was necessary to the existence of contagious fever. He had done 60 post mortems in Frederick Street and found no local focus. He thought that one third of his cases were typhus gravis (probably true typhus), one third synochus (probably Borrelian relapsing fever) and one third typhus mitior (perhaps trench fever). Some, he said, had a typhoid character. This is an early tentative acknowledgement of the work of P. C. A. Louis in Paris, (1829) who distinguished typhoid fever from typhus. Little treated his fevers with tepid sponging, adequate fluids—including 3 to 4 pints a day of infusion of roses—with diaphoretics, “cooling” laxatives, and wine for debility and delirium. He fed them with gruel, panada, and arrowroot with sugar. His mortality was one in 15. Less rationally he used blisters to the neck and turpentine rubs to the chest. Sulphate of quina and aromatic sulphuric acid to hasten convalescence.

Now we come to the best fever physician, J. Seaton Reid. Early in his career he began to distinguish one fever from another. The Union Fever Report 1848 and 49 shows his attempts at classification, and the mortalities. In 1844 he knew, and gave reasons for knowing, that typhus and relapsing fever were different. He observed that an attack of the one did not protect against the other. He observed that the mortality in relapsing fever was less than in typhus, 7% in relapsing fever and 19% in typhus; and relapsing fever he said was more contagious. Many of the hospital staff took it. In 1849 Reid said that there were several separate and distinct species of fever, not counting of course dysentery, small pox, measles and scarlatina. He recognised that the American physicians were ahead of us. They already accepted typhoid as an entity, notably Gerhard in Philadelphia, who had been a pupil of Louis in Paris.

Reid classified fevers so:

Reid 1849.	1987 interpretation.
1. Maculated typhus.	True typhus. Rickettsia prowazekii.
2. The relapsing synocha. A short intense course. Jaundice a fatal complication.	Relapsing fever. Borrelia recurrentis. The yellow fever of Ireland.
3. Synocha or Febricula. The shortest course. Very little risk to life. Begins with a rigor and febrile symptoms. Remits and relapses.	Trench fever. Rochalimæa quintana.
4. Synochus. Often complicated by diarrhœa.	Typhoid fever. Salmonella typhi

Reid's description of synocha or febricula, which I suggest was trench fever, is of the mildest pattern of that infection. But trench fever can run other courses, including a continued fever and a very prolonged relapsing course. Byam, who investigated trench fever in the Great War (1914–1948), thought it possible that “disorderly action of the heart”, an important course of invaliding from the army, might be a sequel of trench fever. The war ended and the question was not settled.

In 1860 Reid said that for the last 9 years he was satisfied that the typhoid fever existed in Belfast. He was certain that he had previously classified many cases of it as synochus. In that year 1860 he said typhoid in Belfast was now more common than typhus. What a revolution in the incidence of disease.

APPENDIX TO MEETING ON 5TH JANUARY, 1867¹

CASE OF OLD STANDING DISLOCATION OF THE HUMERUS.

REDUCTION ELEVEN WEEKS AFTER THE OCCURRENCE OF THE ACCIDENT.

(Read before the Ulster Medical Society.)

By W. MAC CORMAC, M.A., M.D., F.R.C.S.I.;
SURGEON, BELFAST GENERAL HOSPITAL.

The following cases are, I conceive, of sufficient moment to interest the members of the society. I do not, therefore, consider any apology needful in respect of bringing them forward.

The particulars of the first case I have abridged from notes most carefully taken at the time by one of my clinical clerks, Mr. Joseph Smyth, and are as follows:—

George Johnston, 34 years of age, a bricklayer's labourer, was admitted under my care into the General Hospital, Belfast, November 22, 1866.

He gave the following account of how he had met with the accident. Nine weeks since, while "drunk and disorderly," he had fallen into the hands of the police. Considerable violence was required in order to effect his arrest. During the struggle he either fell or was thrown down, and it was then, he believes, that he sustained the injury. His hands were subsequently manacled behind his back, but the pain which this occasioned became so excessive as to necessitate their release.

On the following day, Sunday, as he was suffering very much, his friends thought it expedient to procure medical advice. He was, however, directed merely to stupe the parts with warm water, the nature of the injury, apparently, not having been recognised. Next day the magistrate sentenced him to sixty days' imprisonment. Whilst in gaol, the attention of the surgeon, it appears, was not drawn to the condition of the shoulder. A few days after his time had expired, the man finding himself unable to work, applied to me, and I advised him to go into hospital, which he gladly consented to do.

On examination, the patient was found to be labouring under dislocation of the right humerus, beneath the coracoid process of the scapula, the "infra-coracoid" dislocation of Malgaigne. The acromion process was very prominent, whilst the shoulder had become much flattened, not only from displacement of the head of the bone, but from the atrophy of the deltoid muscles which had ensued. On careful admeasurement, the affected limb was found shortened only one eighth of an inch, while the vertical circumference of the axilla and acromion was increased two inches, a sign first pointed out, and looked upon as a

pathognomonic by Mr. Callender. The fore-arm was in a state of semi-pronation, the arm being directed somewhat backwards, and also slightly abducted. The head of the bone could be felt in the axilla when the arm was raised, but not otherwise. Obscure crepitus, pointed out by Sir Astley Cooper as simulating fracture, could readily be detected by rotating the head of the humerus in its new position.

Although considerable power of motion had been acquired, so much so that the man, whilst in gaol, could pick oakum, and even rake the walks, he could not elevate his injured arm without the assistance of the other arm while the effort occasioned much suffering. He could touch his lips with his fingers, but he could not convey food to his mouth. He had, indeed, to feed himself with the left hand. In short, the limb had become useless to him for the purposes of earning his bread.

On Saturday, the 24th November, precisely ten weeks since the accident had occurred, the man was placed fully under the influence of chloroform, and forcible reduction attempted by means of the pulleys. Extension and counter extension were gradually made, and kept up for a considerable time, with no other effect than breaking down, more or less completely, the new adhesions formed by the head of the bone. The direction of the traction was obliquely downwards and outwards. While the patient was still in an unresisting condition, and the muscles were quite flaccid, before the effects of the chloroform had passed off, White, or La Mothe's plan was tried—the arm being pulled almost directly upwards, the shoulder being depressed by the foot planted firmly against it. The heel was also tried in the axilla. On the 27th, no inflammation or evil effects having followed the previous trial, another effort was made, lasting about half-an-hour, and also under chloroform. Extension was tried in a downward direction, and afterwards manipulation was had recourse to, one hand grasping the head of the bone, whilst the other rotated the arm inwards. The most patient efforts, in this and other ways, obtained no better results than on the previous occasion, and the attempt had, perforce, to be abandoned.

I now almost decided, seeing the risk apt to be incurred from applying so much force, to make no further trial. But an examination of the man's arm, with its almost useless condition, the great and continuous pain which he suffered, especially on trying to raise it, induced me again to make a trial.

Knowing the difficulty of these cases to reside mainly in not employing adequate counter-extension, and sufficiently fixing the scapula, I adopted a suggestion which I owe to Professor Tanner of Cork. It consists in moulding accurately a gutta-percha shield, with a hole in the centre for the arm to protrude, over the back, front, and side of the chest, and round the

¹ [Page 1068. Source: *Medical Press & Circular*, 1867, July 24, p73.]

root of the neck. By this means, the scapula and clavicle were very firmly fixed, and a large surface was available over which to distribute the power employed. The shield was now carefully padded with cotton wool, and re-applied, a sheet passed round it, the arm attached to pulleys above the elbow, and traction so managed as to draw the arm at right angles to the trunk. The fore-arm itself was flexed at a right angle, as well as carefully bandaged. Chloroform having been administered, the pulleys were gradually brought into action for some ten minutes, the humerus at the same time being alternately rotated inwards and outwards. It was then found that the head of the bone had shifted its position externally for fully half-an-inch, and was disengaged from beneath the coracoid, while the adhesions were felt to give way. I now executed the following manœuvre, by means of which I fortunately succeeded in replacing the bone in the glenoid cavity. Firmly depressing the shoulder with my hand, I pulled the neck of the humerus in the opposite direction, by a strap passing round it and over my neck. I requested my colleague, Dr. Murney, who kindly and ably assisted me, to rotate the limb inwards, forcibly, at a given moment. All these preparations having been completed, word was given to let go the pulleys. These were slackened in an instant, when it was found that the head of the bone was in its place. Thus, by means of this combined movement, an old standing dislocation, which had resisted our utmost efforts on two previous occasions, was reduced exactly seventy-seven days after its occurrence.

The shield of gutta-percha was now cut off, while the elbow was kept fixed to the side, and retained there by bandages subsequently sewed together. The skin, which had previously been much abraded by the sheet, was this time unruffled, having been thoroughly protected by the gutta-percha, and that too, notwithstanding the much greater additional force employed. Although the bone was in its place, the prominence of the head, anteriorly, was so marked, as almost to make one fear it could not be so. The muscles around the joint were quite atrophied, causing undue projection of the acromion and spine of the scapula. Nine days after, the bandages were removed, and the patient was allowed to move his arm in a forward direction, as well as to rotate it inwards, but he was enjoined not to exercise it by the reverse movements.

On the 13th I made measurements of the shoulder, and found that the difference of the vertical circumference of the joints had become reduced from two inches to three-quarters of an inch. The transverse diameter of the injured side, taken with calipers, was still one-eighth of an inch greater than the other.

Ten days after, though the man was enjoined to

use his arm, though passive motion was employed daily by myself, I found, on examination, that there was little movement of the arm independent of the scapula, to which it seemed ankylosed. Any attempt forcibly to break down the adhesions, except under chloroform, would have occasioned great pain. The patient, therefore, was put under the influence of the anæsthetic, and having caused my assistants to fix the scapula with their hands, I steadied the head of the bone with my left hand, while I raised the humerus to rather more than a right angle with the other. It was easy both to hear and feel the adhesions giving way, which they did with a peculiar tearing, crackling sound. No inconvenience followed, some temporary soreness excepted, while the additional freedom of action acquired was very considerable.

Before the man had left the Hospital, Jan. 25, 1867, he could readily swing the heavy poker of the ward round his head, stretch both hands equally high against the wall, and perform a number of other feats, which showed that he was rapidly regaining the full power of the extremity. Some months after his discharge, I saw him returning from work carrying a bucket in one hand, and a shovel in the other. He stated that he was always getting more and more command over his arm, and that it was now nearly as useful to him as ever.

Such cases are, in many respects, of great practical importance, and I purposely detained Johnston somewhat longer in hospital than was absolutely necessary, in order that the students might thereby benefit accordingly. In the first place, when the man came under my notice he was quite unaware of the nature of the injury which he had sustained, and his principle complaint was of pain in the neighbourhood of the elbow and fore-arm. He complained of no pain whatever in the shoulder, but only that it was stiff. A short time since, indeed, a carpenter was admitted to hospital with a dislocation of the humerus, which he had believed was a strain, and had treated with liniment conformably; and it was not until nearly a fortnight had elapsed that, finding himself getting no better, he consulted a medical man. Such instances should ensure the exercise of caution in similar circumstances. Great swelling of the soft parts may, and sometimes does, render the symptoms in the event of such injuries obscure; and Hamilton, of New York, mentions two cases in which New York Hospital Surgeons, only a few hours after the receipt of the accident, had failed, from this cause, to ascertain the nature of the injury. In one of these cases reduction was effected by Dr. Hamilton on the seventh, and in the other on the tenth day.

Although, in Johnston's instance, the dislocation was reduced only a week short of the time fixed by Sir Astley Cooper, as the limit beyond which no attempts should be made, many cases are on record where

reduction has been accomplished after much longer periods. It should, however, be remembered that such trials are attended with great risk. Rupture of the axillary artery has but too frequently taken place, and in one instance the nerves of the brachial plexus were actually tom out by the roots. At the same time injurious or fatal results are by no means customarily or uniformly made known.

The force employed on the third trial was simply enormous, and it was all required to pull the bone from beneath the coracoid, and tear up the abnormal adhesions. Its application proved as safe as it was effectual, owing to the equable manner in which the pressure was distributed, and the complete way in which the scapula was fixed by the gutta-percha shield. The principle is the same as that of Sir Astley Cooper's split sheet, but it is vastly more efficient to its employment, indeed, I feel, to a large extent, indebted for the satisfactory issue of the case.

The after progress of the patient was all that could be desired, and the rapid way in which he regained power of motion in the extremity, after such long disuse, was much facilitated by breaking down forcibly the spurious ankylosis between the scapula and humerus, and by the persistent daily employment of passive motion.

In conclusion, I would observe that the forward projection of the head of the bone gradually but not altogether subsided. It is, indeed, important to be aware of this not uncommon occurrence, after reduction of old standing luxations, a circumstance which Hamilton states, has frequently led to charges of malpraxis sometimes successfully, though most unjustly, sustained.

PYÆMIA, WITH EXTENSIVE LESIONS SUPERVENING UPON INJURY OF THE HEAD—DEATH.

The following history serves to show that the body will sometimes be invaded by disease of a most extensive character, and yet the signs of its presence prove very obscure. It presents, as well, some features of medico-legal interest:—

Thomas Gamble, 14 years old, a mill-worker, came under my care in hospital on December 17th. Four days previously, while leaving his work, he was struck on the forehead by another boy with a heavy iron bar some two feet long, inflicting a wound on the forehead, and at the same time knocking him down. The house surgeon dressed the wound, and recommended the lad to remain in hospital, as the pericranium had been stripped off and the bone was laid bare. This, however, the boy at the time refused to do.

When he did seek admission, a vertical wound was found almost in the centre of the forehead, unhealthy looking, and secreting a considerable quantity of pus.

The boy complained of headache, but there was no urgent symptom whatever about the case otherwise.

On the 19th his condition seemed much improved. The wound looked more healthy, and the headache was less.

On the 21st he first complained of his chest. He was annoyed by a short tickling cough, and the sputa were rusty coloured. A stethoscopic examination revealed marked dulness posteriorly over the lower part of the left lung. On the same side in front and above there were great resonance on percussion, and puerile respiration. In the upper part of the right lung well-marked bronchitic râles were heard. He was ordered suitable medicine, and a nourishing diet. Two days after, the 23rd, the chest symptoms became very urgent. The boy's condition was that of a person prostrated with typhoid pneumonia. He was so weak, with a pulse at 125, and hurried, laboured respiration, that it was impossible to make a satisfactory examination. My colleague, Dr. Smith, saw the patient with me on the 25th, and we came to the conclusion that there was evidence of general bronchitis and pneumonia of the lower lobe of the left lung. I need not detail the progress downwards of Gamble's case. He became daily worse and weaker in spite of the most stimulant treatment. He was perfectly sensible and conscious up to his decease. There was no evidence of grave mischief, or any mischief at all, going on within the head, save the headache, which was persistent. He did not even wander in his sleep until the last few nights, and, though very weak, answered any questions put to him in a perfectly collected manner, even when I last saw him alive, on New Year's Eve. He died on the morning of the 1st January, 1867. A post-mortem examination was made fifty-two hours afterwards. The wound was quite unhealed, and its edges blackened from decomposition. On removing the scalp, a groove about an inch and a half in length, involving only the external table, was seen in the frontal bone. It appeared as if made by some blunt instrument. To the right of this groove was a yellow stripe, as if of matter contained in the bone. No fracture or fissure was observed at this time. The calvarium was now removed, whereupon thick yellow pus exuded, through the dura mater, from the anterior part of the right hemisphere, and also lay in contact with the skull. When the membrane was taken off it was found that the entire surface of the right hemisphere was covered with thick greenish-yellow pus, about from two to three ounces in quantity. The anterior convolutions were depressed by it to the extent of quarter of an inch, so as to convey the appearance of loss of substance until the matter had been carefully pressed off with the handle of a scalpel, when they resumed their normal level. There was great congestion of the base of the brain and of the membranes. On section, nothing abnormal was discovered in the interior.

In the left pleural cavity there were found some forty ounces of straw coloured serum. An immense quantity of recent lymph had been poured out. The lower lobe of the lung was solidified, and the upper much congested. On section, a large number of small abscesses were found, perfectly circumscribed, and containing a thick greenish-yellow pus.

In the right lung a similar condition of affairs presented itself. There was not so much serum or lymph, but the abscesses were numerous, and two of them very large.

In the abdomen nothing abnormal could be discovered. On subsequently examining the calvarium, when cleaned, I discovered a minute fissure in the yellow part of the bone, which proved, on section, to contain pus in its diploë. In this way a chain of communication seemed to have been established between the suppurating wound on the head and the other lesions that were found. Purulent absorption had taken place, inducing pyæmia, with purulent depôts or secondary abscesses in the lungs. It is a curious feature in the case, that so little that was indicative of brain disease had attracted attention during the life of the patient. It was remarkable that the brain should submit to so much pressure, that its convolutions should be largely depressed, and that no other symptom should result save headache.

At the trial of the boy who inflicted the injury, the counsel for the defence attempted to prove that the intimate connection between the disorder found in the chest and the injury of the head, as asserted in the medical evidence, was a groundless hypothesis—that the boy had enough of disease in his chest to kill him, independent of the head affection altogether, and that, consequently, no intelligent jury could possibly convict the prisoner of killing my patient. This plea, even had it been sustained, would, however, have been of no legal importance, as, whether the victim of violence be labouring under incurable disease or not, does not affect the legal guilt of the person committing the violence, however it may influence the amount of punishment awarded.

Index

This index concentrates on the presented cases and papers, those presenting, and, if their names were given in full, the patients. Presenters' names sometimes varied from place to place in the text but here they have been standardized.

The aim was to index all cases although it should be noted that some reports are as brief as their index entries. On the other hand, a short entry may sometimes reference a paper several pages long. Generally speaking, no effort has been made to index issues inside papers or arising in the discussions.

Some other activities of the societies have been included but routine day-to-day work has mostly not.

Where possible, indexing in a body system proceeds from proximal to distal, then alphabetically; otherwise alphabetically.

CASES			
BY BODY REGION			
head

parotid

tumour	
_ cartilaginous	707
_ fatty, removed from region of	1049
_ in parotid space	783

oesophagus

foreign body	
_ coin, removed by traction	210
_ large pebble, ejected on induced vomiting	876
_ bougies/brush, for removal of	381
stricture	981
_ for 5 years after swallowing sulphuric acid	1334
_ with ulceration and hæmorrhage	1152
ulceration	395

stomach

cancer	132, 450, 496, 682, 765, 796, 835, 1104, 1337
extraordinarily small	1228
sarcinæ ventriculi	594
parasites	845
perforation	381
_ localised, delayed death	27
ulcer, coats thickened and contracted	1201

liver

abscess	110, 659, 1074
_ ovary affected also	1211
cirrhosis	70, 94, 398, 665
_ in boy aged 16	1049
_ with coma and congestion of large bowel	739
_ with discussion on splenic enlargement,	597
disease	1437
_ dropsy from	1181
_ as a cause of uræmia?	1237
Farre's tubera, with great enlargement	391
_ circumscripta, containing cancer cells	379
_ diffusa	392
fatty degeneration	1293
_ tests for	837

injury

_ laceration, after being run over by cart	776, 1065
_ rupture, from external violence	1231

tumour

_ cancer	117, 1107, 1307
_ malignant disease and abscess	1482
_ left lobe mainly affected, no oil in stools	907

biliary tract

concretions	886
gall-bladder	
_ cystic inflammation, with enlargement of liver	495
_ scarring around galladder	42
tumours, indurated, diffuse, gallstones etc	577
obstruction, jaundice and death	1292

pancreas

tumour of	877
-----------	-----

intestines

calculi, pearl-like, passed from bowel	1109
concretion, intestinal, one of several	532
foreign bodies	163
ileus, use of electro-magnetism in	513
intussusception	1217
_ large bowel, in an infant	43, 875
_ small bowel, in an infant	98
small bowel	
_ inflamed, stomach distended, colon stricture	94
_ perforated ilium, presumed typhoid	655
_ strangulation, internal band	644
_ tumour, ileum, malignant	385
_ ulceration and fistula formation	416
large bowel	
_ destruction, advanced dysentery, in sailor	776
_ prolapse of	983

small and large bowel		ovary	
_ lacerated by gunshot	600	_ cystic	1292, 1346
_ ulcerated following typhoid	388	__ some immense	741
unspecified small or large		__ multi-locular	1219
_ obstruction		__ probably of	1364
__ 2 cases	1241	_ dropsy	869
__ hydrostatic pressure enema in	1241	_ neuralgia	1234
_ ruptured, fall after meal	383	_ removal of	
rectum		__ 2 cases, both fatal	1125
prolapse, after diarrhoea	701	__ first in Belfast but not North of Ireland	1250
stricture, perforated ileum, and abscess	126	_ rupture, leading to death	1293
tumour		_ tumour, scirrhus	1050
_ cancer	727	pessary, in situ for 6 years	673
_ long pedicle, glandular structure	901	pruritus vulvæ	1217
anus		uterus	
artificial, after wound at siege of Lucknow	825	_ and appendages, with large cyst	826
_ spontaneous in strangulated hernia	859	_ compressor, by Pratt of London	497
bodies, leaf-shaped and -sized, passed	779	_ discharge, frequent serous	765
constricted, in child of 10 months	1049	_ displacement of	1471
prolapse of, with prostatic disease	168	_ hæmorrhage	1241, 1455
tumour	660	_ irritable	705
piles		_ phlebitis of, six cases	798
_ 3 cases of	1073	_ small, with enlarged ovary	801
_ internal, ligatured	1156	_ support, utero-abdominal, Hull's	885
omentum		_ tumour	
hydatid disease of	908	__ cancer	583, 1150
peritoneum		__ expelled	1206
ascites		__ fibrous	771, 1118
_ chylous	1477, 1489	___ with swelling of right leg	878
__ death from tuberculous meningitis	1501	___ terminating fatally after pregnancy	1004
_ tapping	597	___ fibro-cystic, occupying abdomen	881
__ 62 times	396	___ with cysts of cervix	1228
__ death from hæmorrhage after	1069	__ fibroid	1292, 1335
arrangement, in mammals and man	1471	___ microscopic specimens	1337
peritonitis	98	__ malignant	1066
_ due to concretion in appendix	164	___ (sent for microscopy but no report)	
_ possibly following perforation	904	__ with pelvic abscesses	1191
		__ polypus	582, 1038
		___ prolapse of pedunculated	779
		__ retroverted	525
		___ treatment by inflating the pelvis	658
		vaginal fistula	
		_ to rectum, successful outcome	495
		_ to bladder	
		__ after difficult delivery, cautery for	491
		__ with imperforate vagina	248
		obstetrics	
		analysis of 900 cases	507
		cervical dilators	
		_ Barnes pneumatic	1502
		_ Hegar's and others	1504
		_ Laminaria digitata	993
		douche	
		_ Hardy's	441
		fœtus	
		_ abnormal	
		__ acephalous	1133

Genital Tract

female

gynæcology

abortion (miscarriage)

 _ after tapping for rapidly increasing effusion 1471

amenorrhœa, protracted 495

cervix

 _ tumour

 __ cancer, microscopic appearance 465

 __ fibrous 1109

Fallopian tubes, dropsy of 1228

labium

 _ syphilis

 __ enlargement 665, 706, 822

 __ morbid mass 658, 681

 _ noma pudendi, treated with strong nitric acid 1200

 _ tumour 426, 988, 1424

fœtus/abnormal/acephalous (continued)			
___ with hydramnios	637, 1232	_ mortality following	1107

_ coma, paralysis, dementia	504 and 605
_ fatal	883
treatment, with dilute nitric acid	493

Injuries

fall down staircase on ship, fatal	835
fatal, with injury to spine	193
gunshot wounds, 2 to leg (same shot), 1 to head	189
head, see cases by body regions/head	
scalp, with skull necrosis	530, 1037
tendon, flexor, removed by machinery	785

Instruments and Appliances

aspirator, Dieulafoy's pneumatic	1148, 1207
bandage, Esmarch's, to restrain hæmorrhage	1199
Bigg of London	
_ arm, artificial	777
_ boot, with artificial ankle-joint	596
_ orthœpede	769
bougies/brush, for foreign bodies in œsophagus	381
chloroform, local, Hardy's apparatus	385
crutch, perineal, invention of the Earl of Antrim	534
cutisector, Piffard's	1147
Daguerreotypes, first mention of use of	392
diagnostic, list of	1466
dilators, Barnes's	1156
douche	
_ eye	
_ _ improved, Cooper's	515
_ _ recommended by Haynes Walton	489
_ obstetric, Hardy's	441
eyelid, granular, Stokes' instrument for	1241
forceps, for epilation, Bayine's	1147
jury-mast, Sayre's, cervical spine disease	1305
microscope, first mention of use of	133
ophthalmoscope	195
optometer, Smee's	515
percutor, spring, Sibson's	381
porte caustique, for spermatorrhœa	383
probe, Nélaton's	1148
plaster jacket, Sayre's, dorsal spine disease	1305
sound, L'Estrange's, measuring bladder calculi	777
sphygmograph, Marey's	1126
spirometers, displayed at conversazione	610
stethoscopes	728
support, utero-abdominal, Hull's	885
syringe	
_ laryngeal, for injecting silver nitrate	381
_ ordinary, in diagnostic aspiration	1252
truss, new form of	120
tube or syringe, minim-graduated, Mr. Alsop's	106
tympenic membrane, artificial, Field's	1241
uterine compressor, by Pratt of London	497
various, for removal of foreign bodies	1004

Mental Illness

asylums, lunatic, appointment of chaplains	136
chloroform, its use in hysteria	907

 median, imbedded in tumour 713
 musculo-spinal, paralysis, 3 cases due to injury 665
 neuroma, causing pain
 _ anterior crural nerve 669
 _ median, ulnar, and internal cutaneous nerves 848
 nerves, idiopathic neuritis 1170
 quinine, its use in sciatica 439
- conditions**
 anæsthesia, thorax, with neuralgic pain 641 and 701
 catalepsy, case of 884
 coma, from uræmia 383
 concussion, after railway accident 1189
 convulsions (not puerperal)¹ 237, 264, 504 and 604, 671, 879
- Jacksonian epilepsy
 _ aura, affecting right thumb 1110
 _ previous head injury 1489
 lateral sclerosis 1471
 neuralgia, intracranial 254

¹ [Convulsions are mentioned 264 times in the text but almost never as the presenting complaint.]

paralysis	
_ ascending, with numbness, after vaccination	1458
_ arms, with intact sensation	666
_ face	
_ disease of external ear and temple	399
_ idiopathic?	381
_ infantile	436
_ pseudo-hypertrophic muscular paralysis	1514
_ in a brother and sister	1456
paraplegia	
_ leg swelling from pelvic tumour	1136
_ well-marked reflex phenomenon	1471
seizure, paralytic, then apoplexy after 4 months	505
tremor, due to mercury	992
weakness, numbness and dementia, progressive	431
instruments	
percutor, spring, Sibson's	381
physiology	
reflexes, patellar, paper on	1445

Respiratory Tract

trachea	
foreign body	868
_ requiring tracheotomy	388
ulceration, extensive, in phthisis	427
bronchi	
bronchitis	
_ including flax related disease	1482
_ with pleuritis, pericarditis, after immersion	122
_ syphilitic, a distinct disease	522
_ with tubercle lung and diarrhoea	128, 129
bronchocele, example of	1023
expectoration/sputum	
_ black, like ink, after gallic acid	524, 532
_ muslin-singer, discussion	437
_ _ microscopy, illustration	464
_ bronchial polypoid formation	435
_ calcareous bodies	417
_ casts	
_ of bronchial tubes	755
_ of trachea, in diphtheria	1036
_ tuberculosis, discussion	408
_ microscopy, illustration	464
lungs	
abscess	519, 1130
apoplexy, pulmonary of Laennec	381
disease, chronic, affecting right heart	878
flax spinning, and mill workers' health	1096, 1482
gangrene	518, 1227
induration, various causes	407
hepatization	1150
malaria [bad air], ship's, causing disease	1018
phthisis/tuberculosis	79, 90, 95, 869, 1231
_ advanced	496
_ catarrhal pneumonic	1331
_ cavitation, with intestinal ulceration	95

_ with cystitis	387
_ disseminated, in a child	22
_ environments	
_ _ climates	1477
_ _ resorts	
_ _ _ Arcachon, Gironde, France	1088
_ _ _ Victoria, Australia	1359
_ with intercurrent pneumonia	517
_ masked by emphysema	711
_ pneumo-thorax, due to	1051
_ rapid progression, emphysema also	590
_ widespread in lungs, liver etc	837
pneumonia	
_ death, very rapid, in a child	1307
_ in children, small frequent doses of mercury	440
_ with pleural effusion and pericarditis	62, 1148
pleura and pleural cavity	
effusion, with hæmoptysis	1016
empyema	
_ 3 year history	853
_ 10 years after, cast of chest and discussion	396
_ in a child	70
_ remarkable case of	1088
_ wet specimens illustrating the effects of	409
loose fibrocalcareous body	519
pleuritis	1241
_ death due to cerebral effusion	420
pneumothorax	
_ with effusion	588, 594
_ tubercular	656
phthisis/tuberculosis, and pleural effusion	827
conditions	
cough, dry, with axillary abscess and pleurisy	131
crepitus, positional pulmonary	1150
dyspnoea, occasional, possible aneurism	1152
instruments	
spirometers, displayed at conversazione	610
physiology	
respiratory excitation and depression	1377

Skin Disease

corn	
containing hair shaft and bulb	607
discolouration	
paper on [no details]	1133
epilation	
Bayine's forceps for	1147
general	
in several children	711
classification, reasons for modifying it	115
perhaps eczema, perhaps psoriasis	882
eczema	
chronic, recurrent, of leg	1489
clinical facts in connection with	444
intractable	835

- eruption**
 remarkable, after potassium iodide 1489
- favus** 1156
 complete cure due to total hair loss 711
- grafting**
 Dr. Murney's cases 1140, 1146, 1219
- ichthyosis**
 no details 878
- impetigo rodens**
 scalp 707
- leprosy**
 with anæsthesia and tubercles 1147
- lupus erythematosus**
 2 cases 1201
 with hypertrophy 20
 nose, destroyed 608
- psoriasis**
 recurrent in early pregnancy 676
 treatment with chrysophanic acid 1293
 _ controlled—applied to one side only 1293
- pemphigus**
 extraordinary case of 975
 gangrenosus 779
- phosphorescent appearance**
 in a child 48
- porrigo**
 Achorion schœnleinii
 _ disease only on chest 767
 _ porrigo favosa 380
 _ _ microscopy, illustration 459
- scleroderma**
 in a male adult 1471
- tumour**
 cancer
 _ epithelial, of hand, 639
 _ of lip 596
 _ _ excellent result after excision 599
 carcinoma, diffuse 713
 cystic
 _ lumbar region, oleaginous fluid 656
 _ small, from between eyes 1181
 epithelioma, of forearm 1147
 gleatomatous 910
 in nævus, profuse hæmorrhage on removal 795
 sebaceous, scrotum 731
 subcutaneous, fatty 642, 649, 673, 681
 _ fibroid blastema 705
- ulcer**
 right temple, ætiology debated 590
- Therapeutics**
drugs
 actea racemosa tincture, in acute rheumatism 880
 alcohol, beneficial? 1278, 1282, 1285, 1288, 1291
 amyl nitrite, cases treated with 1323
 chlorate of potash 710, 1370
 _ therapeutic action 1391
 _ _ in agalacty 1391
 _ _ in galactorrhœa 1392
 chloroform
 _ anæsthetic, general, first mention 92
 _ vs. ether for general anæsthesia 1398, 1403
 _ in hysteria 907
 chrysophanic acid, for psoriasis 1293
 croton chloral, cases treated with 1323
 emetics, therapeutic use 115
 ergot (secale cornutum)
 _ action on the parturient uterus 176
 _ its use in 296 deliveries 996
 _ use and mode of action 994
 ether
 _ anæsthetic, general, first mention 1252
 _ vs. chloroform for general anæsthesia 1398, 1403
 _ Richardson's spray for local anæsthesia 1051
 glycerine and bismuth, curative effects of 1038
 hydrocyanic acid, best mode of administration 576
 hypo-phosphates, in fever 841
 oakum, its use as an antiseptic dressing 1259
 opium, inhaled 581
 pilocarpine
 _ in detachment of the retina 1440
 _ in optic neuritis and intra-cranial disease 1439
 puffball, its hæmostatic qualities 1457
 quinine, its use in sciatica 439
 raspberry leaves, affecting uterine contraction 671
 secale cornutum (see ergot)
 silver nitrate, its use in eye disease 49
 sulphate of zinc, for cancerous ulceration 658
 sulpho-carbolates, in zymotic disease 1383
 whiskey, paper on 1442
- electricity**
 medical uses 250, 585
- Pharmacopœia**
 British, 1864, changes therein 1024
 British, new edition 1079, 1081
 Dublin, new 106
 new, summary of 1037
- poisoning**
 arsenical wallpaper 763
 atropine 1237
 South American poison arrows, still effective 713
 strychnine, with recovery 1437
- research**
 experimental, appeal for 1441
- Urinary Tract**
- kidney**
 analysis of urine, in suppurative nephritis, 733
 anasarca after scarlatina, what is the cause? 438
 Bright's disease 80, 901, 908
 _ anasarca, general, vomiting and death 434
 _ and atrophy, child of 7 910

kidney/Bright's disease (continued)

_ emphysema also	98
_ model, in wax	379
_ phthisis also	97
_ urine, microscopy, illustration	461, 466
calculous, leading to dilation and infection	1467
congenital, horseshoe shaped	1202
disease, unspecified	1150
_ with ascites, anasarca, coma and death	639
enlargement, with anasarca and albuminuria	879
lacerated	1065
morbid parts	884
_ from patient with scarlatina	977
_ dropsical woman who died of influenza	907
tuberculous	
_ pyelitis, scrofulous	1230
_ shown on microscopy	1424
tumour, cystic	1241

ureter

dilatation	1127
------------	------

bladder

calculus	1240, 1241
_ analysis of	434, 600
_ hydrostatic displacement using oral gin	1216
_ measured etc., using L'Estrange's sound	777
_ passed per urethra, with fistula	436
_ removal	
__ Allarton's method	730
__ in a 2 year old	1405
__ lithotomy	1136
___ lateral	1115
__ lithotrity	732, 1364
__ median section	1036 and 1037
cancerous	1230
communication	
_ with sigmoid colon	602
_ with imperforate vagina	248
cystitis	
_ chronic, with pulmonary consumption	125
_ treated with silver nitrate	1209
extroversion	899
_ with epispadias	872
foreign body, removed	775 and 777
inversion	831, 1066
tapped	
_ above pubic ramus	1247
__ leaving indwelling catheter	651
_ per rectum	1247, 1364
thickened, in urinary retention	711
_ and contracted, bilateral hydronephrosis	649

urethra

calculus	644, 709, 1237
_ removed by incision	1231
casts removed from	1424
forceps, Durham's	1237
laceration, from fall	1013
stricture	

_ two in same patient	981
_ discussion regarding	908
_ with enlargement of kidneys	1467
_ operation	
__ Holt's	1000, 1005
__ Syme's operation of perineal section	531
_ spasmodic, after gonorrhœa	433
miscellaneous	
frequency, urinary, with blood	835
calculi, causing dilation of urinary tract	1303
urine	
_ extravasation	1133, 1191
_ chemical and microscopic examination	734
_ retention	4

OTHER ITEMS

Laboratory

arsenic, in wall paper, potential for error in	
medico-legal examinations	427
laboratory, first mention of communication from	434
liver, tests for fatty deposition	837
reports	
_ first mention in a case	
__ chemical	164
__ microscopical	379
_ pathological, earliest extant for Belfast?	865
wine, sacramental, analysis of	984

Miscellaneous

anatomy	
_ anomalies, various	1471
_ notes	1442
_ science, remarks on recent progress of	1140, 1145
antiseptis	
_ Lister's method	
__ rigid use in surgery, first mention of	1350
__ spray, first mention	1262
_ oakum	
__ as a dressing	1258
__ simplifying Lister's method	1261
Aztec children	156
burns, severe, Baradue on cause of death	1007
case, anomalous, in practice	576 and 579
charities, medical, of Belfast, uses/abuses	1410
__ report of committee on	1413
chlorosis, a case of	794
coronership, consideration of	1044
dead, disposal of	1294
death	
_ rate, infantile, of Belfast and suburbs	1386
_ sudden, child, cause uncertain after P.M.	1104
diagnosis, difficulties in, parts I and II	121, 127
differences, mental/physical, man and animals	250

- disease
 _ present asthenic character of 883
 _ various, found in dissecting room 1149
 elk, Irish, vertebræ, rheumatic arthritis 1514
 euthanasia¹ 518
 feeding, per annum, for some months 982
 fees, from life insurance companies 249-250
 fluid, cholesterine, from three cases 606
 fowl gizzard, nail embedded in 642
 Gay, John, dismissal from Royal Free Hospital 159
 Hodgkin's disease, case of 1467
 hospital, new St Thomas', of London 1145
 infants, milk feeding of 1313, 1316, 1320
 inflammation, recent researches on 1036
 medical reform 175
 mill workers health, influence of flax spinning on 1096
 mushrooms, observations on 839
 prisons and prisoners, a paper 1240
 purpura 527, 1471
 recruits, medical examination of 1455
 resuscitation, various conditions in 1018
 revivalism, medical aspects of 222
 shoulder scarves, worn or not at funerals 1298
 soup, for inmates, Deaf and Dumb Institution 999
 ventilation 114
 vital dynamics, recent doctrines in 1119
 wooden cube, swallowed by child, no harm 527

PATIENTS

Anon., first recorded contribution by 1164

Bodel, Mary, born 1839 1211

Bowman, Catherine, born 1808 69

Bryant, Joseph, born 1833 1247

Buchanan, Dr., a non-contagionist who lay on the bed
of a cholera victim and died of the disease 451

Cammrek, John 532

Campbell, Thomas, born 1839 656

Cardwell, Alexander, born 1870 1262

Carty, Peter, born 1858 1061

Carvel, Rebecca, born 1831 659

Chambers, James, born 1823 69

Clark, Bell, born 1770 69

Clarke, John, born 1800 585

Clarke, Martha, born 1799 643

Cochran, Agnes, born 1803 95

Collins, Robert, born 1812 117

Conway, Mary, born 1830 98

Corcorin, Simon, born 1837 1133

Corry, John, born 1809 1134

Coulon, Mr 26

D'Alton, Thomas, born 1836 69

Davis, El., born 1829 69

Davis, William, born 1818 69

Devlin, Margaret, born 1809 779

Dobbin, Daniel, born 1840 1091

Donnelly, Patrick, born 1785, bottler in wine-store 91

Dougherty, Catherine, born 1810 89

Downey, Anne, born 1812 1061

Drain, Daniel, born 1782 97

Drain, James, born 1858 1243

Drennan, William, labourer, born 1816 96

Drummond, Dr. (James Lawson?) 1016

Duffy, Mary, born 1836 1224

Dunlop, J. B., born 1825 874

Dyer, Ann, born 1843 898

Edmonds, Mary, born 1852 1254

Elkin, William, born 1775 651

Elliot, Robert, born 1823 757

Farrell, Isabella, born 1833 705

Ferguson, Ellen, born 1828 97

Gamble, Lizzie, born 1846 1244

Gamble, Thomas, born 1853 1526
